The official regulations establish forty days as the duration of the quarantine of scarlet fever patients. It is the time that must elapse before the child who has recovered from scarlet fever will be readmitted to school. Professor Marfan, writing in the review *Le Nourrisson,* expresses the opinion that the regulations are too rigid and that the duration of the isolation should be determined in each case, for the time when the patient is no longer contagious varies. To appreciate the fact one need only recall that the gravity of scarlet fever and the fear of complications are measured by the intensity of the sore throat. The virus of scarlet fever has its seat chiefly in the throat; hence, as long as the mucosa of the throat is red, swollen and more or less covered with exudates, and as long as the glands of the neck remain frankly palpable, there is justification for the belief that the patient is still contagious, even though the temperature has been about normal for several days. On the other hand, when the throat of the patient has entirely cleared up and the glands of the neck have much diminished in volume, he may be regarded as noncontagious if the temperature is normal, and that stage is reached, in scarlet fever without complications, about the twenty-fifth day. Professor Marfan emphasizes that in all cases the quarantine should continue until the twenty-fifth day. The patient should then be examined as to the condition of the throat, the glands of the neck and the amount of albumin in the urine, if any. If the results are satisfactory, the patient should take a full soap and water bath, and, two days later, or the twenty-seventh day, all the examinations should be repeated. If there is no evidence of an unfavorable change in the patient's condition, he should be required to take a second soap and water bath and put on clean garments, after which he should leave the isolation room, which then should be fumigated and disinfected. In severe, complicated cases of scarlet fever, however, it happens that, even on the fortieth day, the throat has not entirely cleared up, while the adenopathy remains perceptible and the temperature is still above normal, or some complication may be in the course of evolution. Such patients are still contagious and should remain isolated. It will be seen, therefore, that the required period of isolation will vary greatly with the cases; but twenty-five days may be regarded as the minimum. The official period of isolation is thus often too long or too short.

Cancer Week

The custom is growing in France of setting aside, each year, a week to be devoted to propaganda, among the public, in favor of means of combating cancer. Tuberculosis week has become traditional with its sale of tuberculosis seals. Last year the sale of tuberculosis seals produced a profit of 20,000,000 francs ($800,000), which was used in support of the antituberculosis dispensaries or devoted to the erection of sanatoriums. Tuberculosis week furnishes, at the same time, an opportunity of giving advice to the general public by means of the distribution of tracts and the organization of radio lectures on the suitable methods of preventing tuberculosis and of treating it, once it is contracted. There has been, for some time, a mental hygiene week, which, by reason of its too special character, does not appear to have gripped the public. On the contrary, cancer week, which has just been celebrated, awakened great enthusiasm. Another useful week to celebrate in France would be temperance week, in support of the campaign against alcoholism. But there is little likelihood that such a week will be inaugurated, so great is the fear of antagonizing the dealers in alcoholic beverages, whose political influence is great.

Cancer week was the occasion for some remarkable addresses by eminent specialists, usually by the directors of the various anticancer centers of France. Professor Regaud, director of the Curie Institute in Paris, lectured on "How to Prevent and Cure Cancer of the Uterus." He affirmed that this form of cancer, if diagnosed early, and treated with radium or penetrating roentgen rays, would have its mortality reduced to less than one fourth of the present rate. Professor Lambret of Lille spoke on the necessity of early detection of cancer. Professor Sabrazès of Bordeaux spoke on "What Do We Know About Cancer?" He concluded that, while the key to the problem has not been found, worth-while progress has been made. Dr. Jeanneney of Bordeaux discussed "The Causes of Cancer." In the present state of our knowledge, he emphasized that neither heredity nor contagiousness can be regarded as demonstrated, at least not in man, although they have been demonstrated in certain laboratory animals. In view of the existing uncertainty, it is perhaps a good plan for persons to conduct themselves in the same manner as they would if these theories were established, by observing rigorous cleanliness and avoiding marriages between families in which there are numerous cases of cancer on both sides. Professor Imbert of Marseilles reviewed the forms of treatment recommended for cancer—radium, surgery, various medications—and concluded, in line with the other speakers, that their value depended on the promptness with which they were applied—that is to say, on an early diagnosis. Dr. Tisserand of Besançon discussed more particularly the question of uterine cancer and pointed out the magnificent results accomplished by surgery in cases recognized early—

Annual Meeting of British Medical Association

The annual meeting of the British Medical Association was held in London. It was the centenary of the founding of the association.

THE PRESIDENTIAL ADDRESS

In his presidential address, Lord Dawson sketched the progress of medicine during the century of the association's existence. The knowledge of immunity foreshadowed by Jenner, established by Pasteur, and rationalized by Ehrlich and others, had extended. In this country the mantle rests on Wright, who has enriched medicine not only by his discoveries but also by his provocative thought. The study of immunity shows that the remedy lies within man himself—a potential energy which becomes kinetic in the face of the foe. It may be temporarily replaced by serum, but its origin and power must come from the tissues of the body. So it is with the hormone or vitamin which is a determinant of rather than a partner in bodily reaction. In these days the diseases of invasion are receding and the diseases of stress loom larger. A man's physical and mental make-up play no small part in the clinical picture he presents. The mental make-up, inherited and acquired, may color or even confuse the picture presented by a physical illness. There is a fundamental error of thought, that disturbances of the mind are under one's control and therefore are one's fault, whereas disturbances of the body are not under one's control. This false doctrine of control, and all the perversions of the doctrine of free will, with which it has long been entangled, is responsible for much faulty thinking and human suffering.

As to treatment, the mere giving of medicine will often accomplish but little; it is regimen and reeducation that are wanted. A new type of institution, distinct from a hospital, is needed—a health hostel for the overweight person who avows himself a small eater yet is clogged with his own metabolic products, for the various gastro-intestinal victims who need to be taught how to eat, and for the person with early diabetes who needs instruction in food calories. The good of the people demands education in matters of health. The medical faculty of a university could provide approved lectures. For research there is need for further coordination among bodies which represent varied aspects of medical knowledge, such as the basic sciences, medicine, surgery, obstetrics, education and administration. It is a reproach against our profession that we do not establish the means of giving collective advice when government depends increasingly on our knowledge.

THE NONPAYMENT OF PHYSICIANS FOR ROAD ACCIDENTS

At the meeting of the representative body, a motion was submitted urging the government to assume responsibility for the provision of emergency medical treatment in all road accident cases. The reasons given were the alarming increase of these accidents, the growing demands on physicians to render first aid, and the infrequency of payment. Last year 180,000 accidents occurred on the roads. First aid treatment by physicians might save much suffering and much money on the part of insurance companies—a fact which the companies were only beginning to realize—in relation to compensation. It was therefore suggested that the insurance companies might provide a "pool" for this purpose, as they did for fires in connection with the London salvage corps. A woman physician who lived near an important road said that she received payment for only 10 per cent of the accidents which she attended. The motion was referred to the council.

TRIBUTE TO THE FOUNDER OF THE ASSOCIATION

A pilgrimage was made to Worcester to pay honor to the memory of Sir Charles Hastings, a physician of that city, who founded in 1832 the Provincial Medical and Surgical Association, to improve the position and organization of the medical profession. From this association the British Medical Association has developed. The president unveiled a memorial window in the cathedral and a service took place at which Dr. Barnes, F.R.S., bishop of Birmingham, the well known modernist, preached. Having paid tribute to the foresight of Hastings in founding the association and to the great advance of medicine in England during the nineteenth century, he asked: What of the future? They were told to expect increased power to control disease, but his daily experience warned him that we are not safe from religious reaction. The basis of civilization was none too firm, and only by resolute and sustained vigilance could progress be preserved. New aspects of truth often bewildered men and aroused their instinctive opposition. They easily turned to old superstitions slightly disguised and invoked religious sanctions in defense of ingrained prejudices. Our knowledge of human heredity may so increase that we can, by preventing the birth of children to certain persons, raise the quality of our population. Will pseudoreligious prejudice not impede the good work? Religious prejudice gave strength to the clamor against vaccination when first introduced. During the last four centuries the search for truth had been impeded by superstitions and false dogmas.

HOW MAY A SPECIALIST NOTIFY HIS COLLEAGUES THAT HE HAS BEGUN TO PRACTICE?

After considerable discussion it was decided that a specialist may notify his colleagues that he has begun to practice (1) by calling on physicians already established in the area; (2) by sending them a sealed notification, provided there is no laudatory reference to himself; (3) by communications to the local division of the British Medical Association or other medical organization; (4) by sending reprints of his published work to physicians who may be expected to be interested. However, one speaker pointed out that calling on local physicians was a two-edged weapon and might cut off the budding specialist's chances of success. He recalled the fate of two brilliant young men who called in the manner of a commercial traveler. This cost them any chance they had of succeeding.

SHOULD MEDICAL PATENTS BE ALLOWED?

The question whether medical patents should be allowed has given rise to much discussion in the profession. A comprehensive resolution was passed. The meeting was invited to endorse a resolution passed at a joint conference of the Royal Colleges of Physicians and Surgeons and council of the British Medical Association, which declared that the further granting of patents in the medical field is undesirable in the public interest and that any action to prevent or regulate by international action the further granting of such patents would be welcomed. While the meeting was emphatic with regard to bacteriologic products, it was not convinced that the granting of patents for the synthetic preparation of new substances has been similarly detrimental to progress. It was also recognized that a purely national abolition of medical patents might unjustly penalize commercial enterprise in this country. It would gladly see established a mechanism by which patents for preparations other than biologic could be dedicated to the use of the public. It was held that until some such system is established the special position held by physicians in the community renders it undesirable that they should apply for patents in the medical field. Thus this resolution for the first time draws a distinction between bacteriologic and synthetic products.

FOODSTUFFS AND THE CALCIFICATION OF BONE

Prof. Edward Mellanby dealt with foodstuffs influencing calcification. Those stimulating the formation of perfect bone are milk, butter, egg yolk and the fat of meat and fish. All these contain vitamin D, and of these milk, cheese and egg yolk are also rich in calcium and phosphorus. The chief foods hindering calcification are cereals—bread, oatmeal, maize, rice. Other foods which, by stimulating growth and not exerting a corresponding influence on calcification, tend to bring about defective bone formation include lean meat, white fish and most vegetable fats. Vegetables and fruit seem to be more or less indifferent in their action, although in some circumstances the calcium content, especially in the case of green vegetables, may aid calcification. Sometimes green vegetables may even contain a small amount of vitamin D, especially if recently exposed to sunlight. Naturally, also, the vitamin C content of fruit and vegetables prevents scurvy, and thus defends the bones against scorbutic influences. Thus the need for including calcifying foods in the diet is greatest during growth and when cereals are the main constituents of the diet. Since the child's consumption of food is limited, the greater the amount of bread and other cereals eaten the less likely is it that sufficient milk and eggs will be consumed to insure proper bone formation. Further, cereals are the cheapest and therefore the most greatly consumed articles of diet. Climatic conditions in this country are such that the baneful effects of cereals cannot ordinarily be counteracted by ultraviolet radiations. Indeed, all the circumstances—climatic, dietetic and economic—in this country appear to be conducive to defective bone formation. No cereal concoction or cereals ought to be given to an infant for the first eight or nine months, and even after this only in small amounts for the first two years. Cereals form far too great a part of the diet at all ages and might well be replaced to a large extent by milk, eggs, cheese, vegetables and fruit throughout life. The high cost of milk makes a sufficiency difficult for a large proportion of the population; large scale reduction of rickets by increased consumption of milk is therefore unlikely at present. Nor will butter act as a substitute for milk, since in the presence of cereals the antirachitic action of butter is small. But butter can be made much more antirachitic by giving it with additional calcium, 10 per cent calcium phosphate or carbonate. If some means could be found of making butter so that it retained the calcium of the milk, a great advance in the improvement of bone formation would follow.

Quarantine and Scarlet Fever Patients

The official regulations establish forty days as the duration of the quarantine of scarlet fever patients. It is the time that must elapse before the child who has recovered from scarlet fever will be readmitted to school. Professor Marfan, writing in the review *Le Nourrisson*, expresses the opinion that the regulations are too rigid and that the duration of the isolation should be determined in each case, for the time when the patient is no longer contagious varies. To appreciate the fact one need only recall that the gravity of scarlet fever and the fear of complications are measured by the intensity of the sore throat. The virus of scarlet fever has its seat chiefly in the throat; hence, as long as the mucosa of the throat is red, swollen and more or less covered with exudates, and as long as the glands of the neck remain frankly palpable, there is justification for the belief that the patient is still contagious, even though the temperature has been about normal for several days. On the other hand, when the throat of the patient has entirely cleared up and the glands of the neck have much diminished in volume, he may be regarded as noncontagious if the temperature is normal, and that stage is reached, in scarlet fever without complications, about the twenty-fifth day. Professor Marfan emphasizes that in all cases the quarantine should continue until the twenty-fifth day. The patient should then be examined as to the condition of the throat, the glands of the neck and the amount of albumin in the urine, if any. If the results are satisfactory, the patient should take a full soap and water bath, and, two days later, or the twenty-seventh day, all the examinations should be repeated. If there is no evidence of an unfavorable change in the patient's condition, he should be required to take a second soap and water bath and put on clean garments, after which he should leave the isolation room, which then should be fumigated and disinfected. In severe, complicated cases of scarlet fever, however, it happens that, even on the fortieth day, the throat has not entirely cleared up, while the adenopathy remains perceptible and the temperature is still above normal, or some complication may be in the course of evolution. Such patients are still contagious and should remain isolated. It will be seen, therefore, that the required period of isolation will vary greatly with the cases; but twenty-five days may be regarded as the minimum. The official period of isolation is thus often too long or too short.

Cancer Week

The custom is growing in France of setting aside, each year, a week to be devoted to propaganda, among the public, in favor of means of combating cancer. Tuberculosis week has become traditional with its sale of tuberculosis seals. Last year the sale of tuberculosis seals produced a profit of 20,000,000 francs ($800,000), which was used in support of the antituberculosis dispensaries or devoted to the erection of sanatoriums. Tuberculosis week furnishes, at the same time, an opportunity of giving advice to the general public by means of the distribution of tracts and the organization of radio lectures on the suitable methods of preventing tuberculosis and of treating it, once it is contracted. There has been, for some time, a mental hygiene week, which, by reason of its too special character, does not appear to have gripped the public. On the contrary, cancer week, which has just been celebrated, awakened great enthusiasm. Another useful week to celebrate in France would be temperance week, in support of the campaign against alcoholism. But there is little likelihood that such a week will be inaugurated, so great is the fear of antagonizing the dealers in alcoholic beverages, whose political influence is great.

Cancer week was the occasion for some remarkable addresses by eminent specialists, usually by the directors of the various anticancer centers of France. Professor Regaud, director of the Curie Institute in Paris, lectured on "How to Prevent and Cure Cancer of the Uterus." He affirmed that this form of cancer, if diagnosed early, and treated with radium or penetrating roentgen rays, would have its mortality reduced to less than one fourth of the present rate. Professor Lambret of Lille spoke on the necessity of early detection of cancer. Professor Sabrazès of Bordeaux spoke on "What Do We Know About Cancer?" He concluded that, while the key to the problem has not been found, worth-while progress has been made. Dr. Jeanneney of Bordeaux discussed "The Causes of Cancer." In the present state of our knowledge, he emphasized that neither heredity nor contagiousness can be regarded as demonstrated, at least not in man, although they have been demonstrated in certain laboratory animals. In view of the existing uncertainty, it is perhaps a good plan for persons to conduct themselves in the same manner as they would if these theories were established, by observing rigorous cleanliness and avoiding marriages between families in which there are numerous cases of cancer on both sides. Professor Imbert of Marseilles reviewed the forms of treatment recommended for cancer—radium, surgery, various medications—and concluded, in line with the other speakers, that their value depended on the promptness with which they were applied—that is to say, on an early diagnosis. Dr. Tisserand of Besançon discussed more particularly the question of uterine cancer and pointed out the magnificent results accomplished by surgery in cases recognized early—

hence the advice given women of seeking an examination twice a year, with this object in view, by the surgeon, and especially on the appearance of any irregular hemorrhage. Dr. Degrais, specialist in radium therapy, spoke on this treatment, which is so often effective in skin cancers. Professor Hartmann, whose opinion in these matters is universally recognized, took as his subject "We Must Cure Cancer Patients," an encouraging slogan, in support of which he introduced the most precise statistics. Professor Forgue of Montpellier spoke on the topic "What Every Woman Should Know Concerning Cancer of the Uterus." Dr. Gunsett of Strasbourg uttered warnings against illusory methods of treating cancer. In France today a great many persons are taking magnesium salts, concerning the value of which there has been much publicity in the press, with many references to the laboratory experiments of Delbet, and imagine that they are thus fully protected against cancer. Professor Lambret cited the case of a patient in whom he diagnosed cancer of the breast, whereupon the patient replied that the diagnosis could not be correct, for she had been taking magnesium salts daily. Furthermore, Professor Sabrazès declared that, during the five year period that has elapsed since this medication was adopted by hundreds of thousands of persons, the cancer rate has not diminished in the slightest.

BERLIN

Cancer Research

The Berliner Verein für Innere Medizin held recently a joint session with the Deutsches Zentralkomitee zur Erforschung und Bekämpfung der Krebskrankheit, which offered an opportunity to consider the present status of the cancer problem from its various sides.

Professor von Bergmann, the chairman, outlined a significant program for cancer research. He emphasized that in waging a crusade against cancer every individual scientific research will, in the end, be more significant and more successful than the greatest organizations, which have, to be sure, a pious desire but have not as yet the power of accomplishment.

The various addresses showed plainly that, in recent decades, the work in the field of tumor research has taken on a peculiar aspect. Tumor research is today no longer dependent on other fields to which it was formerly attached and from which it was derived, but it has now its own methods and has, without doubt, already enriched all branches of medicine, and particularly biology, with many important ideas and conceptions.

Dr. Hans Laser, of the Heidelberg institute for cancer research, was the first speaker on the program and discussed "Manometric Measurements of the Metabolism of Tissue Cultures." In harmony with the methods with which Otto Warburg obtained his famous results, he developed very exact and delicately elaborated methods of solving the quantitative problem, which is difficult of approach.

The second speaker, Frederick L. Hoffman, reported on "Recent Results of the Special Cancer Census in San Francisco."

Professor Caspari of Frankfort-on-Main considered "Nonspecific Immunity in Cancer, and the Significance of Necrohormones." Caspari presented the views in this field, which he has been studying for thirty years. He believes that the definitive healing of cancer, either through ray treatment or through operation, depends to a great extent on the so-called nonspecific defense reactions of the body, which are produced by the degeneration of the tumor cells and by the irritating substances given off by them to the body. That is the only explanation for the healing of tumors in spite of the fact that ray treatment does not, by any means, kill all the tumor cells. For the practical evaluation of these points of view, quantitative researches are urgently needed. Caspari did not depart from the realm of theory and refused to apply his theories to modern practice, leaving that to the future.

Before closing the session, Dr. Höfer of Berlin presented a cinematographic film of a tissue culture of human cancer cells.

Tomatoes and Cancer

The select committee of the Deutsches Zentralkomitee zur Erforschung und Bekämpfung der Krebskrankheit has studied the question that has been circulating among the people for some time as to whether the eating of tomatoes has any causal connection with the genesis of cancer. Recent scientific studies have not established anything positive. Various observations—the heavy consumption of tomatoes in Spain and the beneficent effects of tomato juice in the diet of infants—are likewise opposed to such an assumption. The committee reached the conviction that there is no reason for making the eating of tomatoes responsible for the genesis of cancer.

Is Sterilization an Injury in the Legal Sense?

Recently, the small city of Offenburg in Baden witnessed the trial of a case of great importance, and one that is awakening interest among physicians and the public. The trial resulted in a prison sentence of one year for Medizinalrat Merk (aged 60), the director of the municipal hospital in Kehl, for infliction of bodily injury, and likewise imposed prison sentences on two physicians of Kehl as his aids. It has opened a new problem for the medical and legal professions in Germany: Is medical intervention on a woman's body for the purpose of effecting sterilization punishable by law?

The director of the gynecologic institute in Berlin, Professor Liepmann, who was an expert witness in the case, deserves commendation for having recognized the fundamental importance of the Offenburg transactions and for having arranged for their discussion at his institute Doubtless most gynecologists have never surmised that such an operative intervention renders the operator liable to prosecution in the courts.

After Director Schmitz, of the Berlin Landesgericht, had discussed the problem of sterilization from the legal side, it was considered from the medical point of view by Professor Liepmann. In the case of the condemned Medizinalrat Merk, it is not a question of a careless or overzealous experimenter but of an experienced and skilled operator, whose interventions had always been successful. Forty-one cases of artificial sterilization were charged against him, although not one of his patients had suffered any injury, in the ordinary sense of the word. Furthermore, the condemned man is the government medical officer of the district, who was filled with a sense of responsibility in performing the duties of his office and was actuated by a readiness to relieve human suffering, which characterizes his profession. Precisely this situation of affairs enhances the fundamental significance of this case.

In a closing statement, Director Schmitz called attention to the fact that the trial judge had shown a wide understanding for the problem, as could be seen especially by the fact that he had taken a broad view of the matter and had not accepted the idea of a "severe bodily injury," which the penal code puts down as a penitentiary offense, but had only assumed a dangerous bodily injury.

Artificial sterilization of women, Professor Liepmann explained, is permissible if it is performed with a specific therapeutic purpose in view; for example, in connection with the removal of a cancerous tumor or a tuberculous focus. But this conception of a therapeutic purpose is not clearly defined from the medical point of view. It is certain, however, that the guilt of the physician is established if the artificial sterilization was performed solely for the purpose of making the woman sterile. In none of the forty-one cases, which constituted the charge against the defendant in the Offenburg trial, was that the case. But the court was convinced that Medizinalrat Merk did not always inquire zealously enough into the cases. Although the director of a hospital, he had to work without the aid of an assistant director and therefore had no time to write case histories. The court held that against him as a serious matter. Although the justification of the decision did not take such a narrow view of the conception of a therapeutic purpose, yet the trial judge thought that in a number of sterilizations the therapeutic purpose was not clearly in evidence. It is an offense against good morals, the justification sets forth, to perform a sterilization when the purpose is to obtain relief from the duties of conjugal and family life. There is grave danger that sterilized women may be led into dissolute ways and to undue yielding to their sexual desires. But the patients of the Kehl physician were without exception poor, anemic women of the proletariat class. There is another point: the consent of the patient to the surgical intervention has no bearing, according to the existing laws, on the guilt of the operator; even though the patient gave her consent, the offense against good morals still stands.

The judgment of the Offenburg trial has revealed a complete confusion of ideas. What will the eugenists and the promoters of race hygiene have to say, who, in the interest of public health, demand the sterilization of persons whose progeny is likely to constitute a menace to the public welfare? Such criminal prosecution of physicians for performing sterilization concerns the fundamental rights of the medical profession, and raises the question, as Director Schmitz formulated it: What is the basis of a physician's right to operate and by what legal provisions is that right assured? Here is an evident omission in the existing penal code, nor is the omission fully covered by the improved regulations of the new draft of the code. The Offenburg trial shows, at the same time, under what difficult conditions respected and honorable physicians must work and what causes may give rise to serious charges and the imposition of fines or a prison sentence.

BUCHAREST

(From Our Regular Correspondent)

July 21, 1932.

Tabetic Optic Nerve Atrophy

Dr. Joseph Hamburg, chief ophthalmologist to the Jewish hospital at Cluj, Rumania, carried on extensive experiments with the treatment of optic nerve atrophy by increasing cell oxidation. News of his achievements with this treatment reached the Vienna Ophthalmologic Society and resulted in an invitation to lecture. He did so, May 23. His report was favorably received and his method now is being used by some of the most prominent ophthalmologists of Vienna. In his investigations, Hamburg was led by the following reasoning: The therapeutic methods employed in this disease have aimed mainly at breaking through the blood vessel and nerve sheaths. According to the investigations of Igersheimer the spirochetes do not stay in the nerve itself but in the meninges and the adventitiae of the nerves and vessels, wherefore attacks against the barriers do not seem to be practical. These observations of Igersheimer support the theory that in the development of the disease some toxic components are indirectly acting on the spirochetes. The manner of action of these toxic factors is unknown. According to Dr. Hamburg this is the main point of the whole tabes question. He studied other toxic optic nerve atrophies. Methyl alcohol poisoning conforms with tabetic optic atrophy in many points. Knowledge of the chemical mechanism of the poisoning action in methyl alcohol intoxication is valuable in this analogy. In cases of methyl alcohol poisoning there is a reduction of the cell oxidation, provoked by the disturbance caused by heavy metal catalysis. Hamburg assumed that in cases of optic nerve atrophy a similar toxic action prevails and he tried to influence the morbid process by the administration of drugs that are capable of exaggerating oxidation, as thyroid hormone and manganese.

The best results are achieved by administering intramuscular injections of solution of potassium permanganate, 1 cc., or one or two thyroxine injections, given intravenously. He himself applied in the majority of cases potassium permanganate and only in a few cases thyroxine. By applying potassium permanganate he observed some by-effects, which, however, are not annoying. The principal by-effect is the acceleration of the pulse, sweating, and in some cases light trembling of the limbs, a curious coincidence reminding one of exophthalmic goiter. Besides these manifestations some patients complain of moderate pains in the lower limbs and joints, localizing these to the bones. Injections of thyroxine are not accompanied by such severe by-effects, and, if there are any, they are of short duration.

According to Hamburg, the visual power of tabetic patients is greatly influenced by physical work. The optimum of their visual power is found in the morning. Bodily work involves the consumption of oxygen and thereby the existing lack of oxygen is increased. He deems it important that tabetic patients should observe the rule of the strictest rest, particularly if they suffer from optic atrophy.

He treated seven patients. In five of these a considerable improvement could be noticed. In one of the cases the visual power rose from 3/50 to 3/12. The visual field increased three or four fold, and color vision returned. In another case the visual acuity improved from 1/35 to 1/10 and in the left eye from 1/50 to 1/10, with considerable increase of the visual fields on both sides. The white color limit extended fourfold. The third patient had an improvement of the visual power from 1/36 to 1/12 on the right side and from 1/36 to 1/16 on the left side, with an unchanged visual field. In the fourth case the visual power rose from 3/25 on the right side to 3/10 and on the left from 5/40 to 5/16. The right visual field was expanded to white color, and the blue-yellow sensation returned; on the left side the blue field was considerably expanded. In the fifth case light perception rose from 1 to 6 meters and also the seeing of hand motion improved.

Even if this slight gain does not mean much for the patient, the case should be evaluated as "positive." In two cases the visual power decreased after a transitory improvement. One of these patients was a child suffering from congenital syphilis.

Five of seven cases showed a decided improvement. It can be stated without undue optimism that the improvement could be ascribed to the treatment. It is safe to say that however skeptical one is, and in tabetic optic atrophy one must be skeptical, thyroxine and manganese, by increasing oxidation in the cells, are capable of favorably influencing tabetic optic atrophy. It needs further experimentation, and it will be a long time until final conclusions as to the definite results of this therapeutic method can be drawn.

Marriages

Howard E. Mathay, Youngstown, Ohio, to Miss Mary Siple of Cleveland, in Staunton, Va., August 3.

Edward Lawrence Voke, Akron, Ohio, to Miss Julia Eleanor Morton of New York, July 9.

Nathan Palmer Fitts, Williamsburg, Va., to Miss Lucille Branderberger of St. Louis, July 12.

Oscar Walter Friske, Beloit, Wis., to Margaret Hall Schulmeyer of Indianapolis, July 27.

Charles Harold Spiggle, Strasburg, Va., to Miss Ann Margaret Chiles, July 20.

Douglas Nelson Gibson to Miss Marcella Powell, both of Des Moines, in July.

Stewart M. Gibson, Southbridge, Mass., to Miss Bernice G. McGilvray, July 30.

Elmer W. Nahrwold to Miss Magdalen Lange, both of St. Louis, August 4.

Ruth Foljambe, Boston, to Mr. George Rogers Copeland, July 23.

Deaths

John George Spenzer ⊕ Cleveland, Medical Department of Western Reserve University, Cleveland, 1884, instructor in pharmacology at his alma mater and professor of chemistry at the dental school, 1894-1896, professor of general and medical chemistry and pharmacology at the Cleveland College of Physicians and Surgeons, Medical Department Ohio Wesleyan University, 1896-1910, professor of chemistry, legal chemistry and medical jurisprudence at his alma mater, 1910-1917, aged 67, died, July 26, in the Cleveland Clinic Hospital, of diabetes and prostatic hypertrophy.

Samuel Wyllis Bandler, New York, College of Physicians and Surgeons in the City of New York, 1894, member of the Medical Society of the State of New York and the American Association of Obstetricians, Gynecologists and Abdominal Surgeons, fellow of the American College of Surgeons, formerly professor of gynecology at the New York Post-Graduate Medical School, author of 'Medical Gynecology,' aged 62, died, July 31, at his summer home in Scarsdale, N. Y.

Joseph Marion Little, Pana, Ill., Missouri Medical College, St. Louis, 1899, member of the Illinois State Medical Society, medical superintendent and owner of a sanatorium bearing his name, aged 64, was instantly killed July 11, when the automobile in which he was driving was struck by a train.

Cassius True Lesan ⊕ Mount Ayr, Iowa, Rush Medical College, Chicago, 1897, member of the state department of health, for many years county coroner and city health officer, served during the World War, aged 58, died, July 9, of arteriosclerosis and uremia.

Pennuel Columbus Worley, Shreveport, La., Memphis (Tenn.) Hospital Medical College, 1899, member of the Louisiana State Medical Society, aged 59, died July 21, in the North Louisiana Sanitarium, of acute intestinal obstruction.

Henry Franklin Wilkins, Birmingham, Ala., Medical College of Alabama, Mobile, 1893, aged 62, died, July 17, in the United States Veterans' Hospital, Alexandria, La., of chronic encephalitis with parkinsonian syndrome.

William Osborn Lambly ⊕ Lebanon, N. H., McGill University Faculty of Medicine, Montreal, Que., Canada, 1894, aged 60, died, May 17, at the Mary Hitchcock Hospital, Hanover, of acute hemorrhagic pancreatitis.

Hugh H. Atkinson, Indianapolis, University of Pennsylvania School of Medicine, Philadelphia, 1898, formerly on the staff of the Central State Hospital, aged 61, died suddenly, July 2, of angina pectoris.

Charles William Demong, Syracuse, N. Y., Syracuse University College of Medicine, 1906, member of the Medical Society of the State of New York, aged 50, died, June 25, of mitral insufficiency.

John Isaac Davis, Oteen, N. C., Ohio Medical University, Columbus, 1894, for several years on the staff of the U. S. Veterans' Hospital number 60, aged 63, died, July 5, of chronic myocarditis.

Homer Isaac Rexford ⊕ Willard, N. Y., Albany (N. Y.) Medical College, 1915, served during the World War, on the staff of the Willard State Hospital, aged 41, died, July 11, of aplastic anemia.

F. S. LeRoy Holmes, Kemptville, Ont., Canada, Queen's University Faculty of Medicine, Kingston, 1877, medical health officer for Kemptville and district for many years, died recently.

James E. Burgess, Detroit, Michigan College of Medicine and Surgery, 1893, for twenty years county coroner, aged 65, died, July 6, at his summer home near Pontiac, Mich., of heart disease.

Thomas Heisler Chattle, North Bay, N. Y., University of Vermont College of Medicine, Burlington, 1887, served during the World War, aged 68, died, July 8, of heart disease.

Rozel M. Curtiss, Marengo, Ill., College of Physicians and Surgeons, Chicago, 1884, Chicago Homeopathic Medical College, 1885, aged 76, died, July 3, of angina pectoris.

Marion A. Emshwiller, Montpelier, Ind., Medical College of Indiana, Indianapolis, 1891, served during the World War, aged 62, died, June 30, of carcinoma of the duodenum.

Frank W. Mitchell, Medford, Wis., Chicago Physio-Medical Institute, 1887, member of the State Medical Society of Wisconsin, aged 68, died, July 1, of heart disease.

Cornelius Joseph Egan ⊕ New York, New York University Medical College, 1897, aged 64, died, June 26, in the Royal Hospital, of acute gangrenous cholecystitis.

Charles J. Scott, Marietta, Ohio, Jefferson Medical College of Philadelphia, 1881, member of the Ohio State Medical Association, aged 74, died, June 24, of typhoid.

Hunter J. Duvall, Hutchinson, Kan., Kansas City Medical College, 1894, member of the Kansas Medical Society, aged 65, died, June 27, of carcinoma of the prostate.

George Young Hord, Keyesport, Ill., Medical College of Ohio, Cincinnati, 1878, formerly postmaster of Keyesport, aged 83, died, June 21, of carcinoma of the liver.

Donald Mackintosh, Pugwash, N. S., Canada, Harvard University Medical School, Boston, 1871, L.R.C.P., Edinburgh, Scotland, 1873, aged 84, died, February 10.

Donald D. Salley, Cope, S. C.; Vanderbilt University School of Medicine, Nashville, Tenn., 1894, aged 62, died, June 16, in a hospital at Orangeburg.

Benjamin Franklin Houston, Corsicana, Texas, Medical Department University of Tennessee, Nashville, 1887, aged 79, died, May 26, of brain softening.

David Joseph Herlihy, Cambridge, Mass., Tufts College Medical School, Boston, 1916, served during the World War, aged 38, died, June 12, of pneumonia.

Clarence Allen Copeland, Philadelphia; University of Pennsylvania School of Medicine, Philadelphia, 1919, aged 45, died, June 26, of cerebral hemorrhage.

Rowland I. Haines, Pitman, N. J.; University of Pennsylvania School of Medicine, Philadelphia, 1890, aged 64, died June 25, of carcinoma of the rectum.

John Thornton Sibley, Los Angeles; American Medical College, St. Louis, 1874, aged 80, died, May 15, of softening of the brain and arteriosclerosis.

Abner O. Clark, Ridge, La., Medical Department of the Tulane University of Louisiana, New Orleans, 1887, aged 73, died, June 27, of heart disease.

Harry Bosworth Crocker, San Francisco, California Eclectic Medical College, Los Angeles, 1900, aged 55, died July 6, of cerebral hemorrhage.

Park M. Lehman ⊕ Ney, Ohio, Starling Medical College, Columbus, 1888, for thirty-five years postmaster, aged 74, died, July 9, of heart disease.

Agnes Walker ⊕ Bolinas, Calif., Cooper Medical College, San Francisco, 1893, aged 57, died, June 7, in San Francisco, of carcinoma of the liver.

Herman R. Russell, St. Paul, College of Physicians and Surgeons, Chicago, 1899, aged 60, died, June 29, in St. Luke's Hospital, of heart disease.

John M. Floor, Petersburg, Ohio, Eclectic Medical Institute, Cincinnati, 1875, aged 79, died, July 4, of injuries received in an automobile accident.

Joseph Powell Speight, Rocky Mount, N. C., Jefferson Medical College of Philadelphia, 1906, aged 47, died suddenly, July 29, of heart disease.

Gilbert N. Bailey, Baileyton, Tenn. (licensed, Tennessee, 1889), aged 65, died, July 5, of hypertrophic osteo-arthritis and chronic myocarditis.

James William May, Headrick, Okla. (registered in Oklahoma by the state board of health under the Act of 1908), aged 52, died, July 11.

Daniel F. Shipley, Westminster, Md., Hahnemann Medical College of Philadelphia, 1882, aged 76, died, July 9, of heart disease.

Thomas F. Bray, Reed City, Mich., Hospital College of Medicine, Louisville, Ky., 1894, aged 63, died, June 29, of heart disease.

Rose F. Jackson, St. Petersburg, Fla., Cleveland Homeopathic Medical College, 1899, aged 62, died, July 6, of chronic nephritis.

Jefferson Davis Austin, Clinton, S. C., Atlanta Medical College, 1885, aged 71, died, July 21, of arteriosclerosis.

Charles Frank Elrod, Chariton, Iowa (licensed, Iowa, 1886), aged 83, died, May 15, of cerebral hemorrhage.

Ernest D. Starbird, Denver, Gross Medical College, Denver, 1902, aged 59, died, June 12, of pneumonia.

Elmer G. Gray, McComb, Ohio, Columbus Medical College, 1892, aged 65, died, June 26, of heart disease.

C. C. Bruton, Nella, Ark. (licensed, Arkansas, 1903); aged 80, died, June 5, of senility.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed Every letter must contain the writer's name and address, but these will be omitted, on request

ABDOMINAL PAIN OF UNKNOWN ORIGIN

To the Editor—I have a patient who had a severe attack of abdominal pain in the lower part of the abdomen two weeks ago, following a ride on horseback of 7 miles There was nausea and vomiting of a severe nature He has had several attacks of this 'acute indigestion," as he calls it in the last few years Morphine, one fourth grain (16 mg), was required to relieve this pain He is a white man, aged 55 The physical examination revealed nothing at that time except some tenderness in the lower quadrants, most marked in the lower left Three days later the prostate was examined It was smaller than normal, and some soft areas were present The smear showed a few pus cells, with much granular debris, some corpora amylacea and a few prostatic granule cells There is no increase in the sensitiveness of the gland One week later he reported that he was feeling better than he had felt in six weeks and had gained 5 pounds (2 3 Kg) The prostatic smear at this time showed many clumps of pus cells and myriads of single pus cells It was no more tender than the normal gland One week later he reported that he had another attack, following a ride of 7 miles in a wagon This attack was not as severe as the first one two weeks before The prostatic smear at this time shows many pus cells, but no clumping of the pus cells Am I justified in making a diagnosis of chronic parenchymatous prostatitis? There are no symptoms of tuberculosis in the lungs or elsewhere Is prostatic massage contraindicated in a man of this age? What are the age limits for massage, if any? Please omit name and address

M D, Tennessee

ANSWER—The history of a severe attack of abdominal pain associated with nausea and vomiting, and the fact that it was necessary to give morphine to relieve this pain, leads one to make a diagnosis of abdominal colic The three common causes of abdominal colic of this severity are gallstone colic, kidney or ureteral stone colic, and intestinal colic Furthermore, in view of the fact that the patient has had several attacks of colic described as "acute indigestion," a careful examination to determine the cause of these attacks of pain should be made A plain roentgen examination of the urinary tract should be made to determine the presence or absence of stone, and if negative an intravenous pyelogram may be made If stone in the urinary tract has been ruled out, the next step would be the study of the gallbladder with plain films and with a cholecystogram Failure to obtain information from these two sources would justify a careful examination of the gastro-intestinal tract It is necessary, of course, in this differential diagnosis to rule out tabes dorsalis

From the further description it is evident that the patient has a mild chronic prostatitis This should be treated with gentle massage of the prostate at weekly intervals Heat by rectum or hot sitz baths are desirable The diagnosis of prostatitis is probably justified Prostatic massage is not contraindicated in this patient, and we know of no age limits for massage Nothing is stated regarding the condition of the patient's seminal vesicles Occasionally renal colic may be due to a chronic seminal vesiculitis with periseminal vesiculitis and involvement of the ureter

PULMONARY CONDITIONS IN RHEUMATIC FEVER

To the Editor—A boy, aged 15 years, suffering from rheumatic endocarditis with aortic insufficiency, had a form of fibrinous bronchitis, last year, with spitting up of bronchial casts at intervals of one week or one month On microscopic examination no bacilli of diphtheria or of tuberculosis were found on them The cardiologist who was treating him at that time excluded the hypothesis that the fibrinous bronchitis was due to circulatory stasis in his lungs Now the boy is suffering again from the same type of cough with spitting up of bronchial casts, and the cardiologist who is attending him now, in Europe, thinks that this type of bronchitis is due to the circulatory stasis in the lungs and therefore a sign of decompensation of the heart I looked up the literature on the subject and found that fibrinous bronchitis is sometimes due to circulatory disturbances from mitral stenosis, and this patient positively never had any mitral stenosis Could you give me your opinion or any reference I could look up? Please omit name

M D, New York

ANSWER—The pulmonary conditions associated with rheumatic fever and rheumatic endocarditis constitute an interesting diagnostic problem, about which varying views have been held for a long time Cheatle mentions several cases of pneumonia associated with rheumatic heart disease in his classic lectures on rheumatic fever No better clinical description can ever be written than Broadbent's

Among the pulmonary changes associated with rheumatic fever and rheumatic endocarditis may be mentioned (1) pulmonary compression associated with dulness and bronchial breathing at the left base, (2) pleural fluid associated with pulmonary compression at the bases, or pericardial effusion, (3) pulmonary infarction secondary to mural thrombi or to rheumatic phlebitis, (4) chronic passive congestion of the lungs as a result of impaired pulmonary circulation, (5) rheumatic pneumonia associated with histologic changes in the walls of the pulmonary arteries and perivascular spaces, and, finally, (6) frank bronchopneumonia occurring as an intercurrent infection at any stage of rheumatic fever

If these possibilities are reviewed in association with the physical phenomena observed in this case, a conclusion can probably be reached as to the origin of the fibrinous casts An excellent review on this subject is contained in the article entitled "Pleural and Pulmonary Lesions in Rheumatic Fever," by John R Paul (*Medicine* **7**:838 [Dec] 1928)

ECZEMA OF AUDITORY CANALS

To the Editor—A man has what I call weeping eczema of both external auditory canals He has had considerable trouble in the past with the wax hardening and packing right in the canal There is also in this wax considerable desquamation I have tried washing out with many kinds of antiseptic as well as plain salt water but yet the canal fills right up again with the wax and desquamation I have used ointments and have tried 25 per cent silver nitrate solution It is the most persistent thing I have ever seen The patient never has eczema in any other part of the body and enjoys good health generally

E B MINOR M D, Traverse City, Mich

ANSWER—It is assumed that no middle ear infection is present, draining into the canal and keeping up the irritation The silver nitrate was used in too strong a solution One might try swabbing the ear dry and painting the canal with 2 per cent solution of silver nitrate once a day then applying a thin layer of zinc oxide ointment, or swabbing it clean once or twice a day and applying

	Gm or Cc	
Rectified oil of birch tar N F	1 6	♏ xxv
Resorcinol	8	gr xiii
Liquid petrolatum sufficient to make	16	℥ ss

If these measures fail, roentgen rays may be tried by an expert This should not be continued after the eczema clears up or in any case more than eight weeks

SYPHILIS WITH POSSIBLE OPHTHALMIC MANIFESTATIONS OF OTHER DISORDERS

To the Editor—I have a patient with the following history There was a primary sore on the penis twenty years ago The Wassermann reaction at that time was four plus Treatment at that time consisted of mercury, mostly by mouth with a few intramuscular injections during the latter part of the treatment One treatment with arsphenamine was given several years ago When seen a few weeks ago the patient complained of slight headache and the vision was a little defective On physical examination the majority of reflexes were hyperactive The right pupil was regular in outline and responded well to light and in accommodation The left pupil was irregular in outline was smaller than the right and reacted very poorly A spinal puncture was done in the lower lumbar region and the fluid came out in an almost solid stream No manometer was at hand, so the pressure was not taken The 20 cc of fluid that was withdrawn was divided into two portions and sent to two reliable laboratories The first laboratory reported 2 leukocytes globulin negative, total protein 25 mg per hundred cubic centimeters Wassermann reaction negative, colloidal gold curve 1111100000 The second laboratory reported the colloidal gold curve 1110000000 gum mastic 1100000000 The Pandy test was negative Please advise treatment in this case Kindly omit name and address

M D Ohio

ANSWER—With what appears to have been a negative spinal fluid with respect to syphilis, this patient's probable diagnosis suggested by the headache, visual disturbance, pupillary changes and high fluid pressure is a localized syphilitic or other cerebral lesion, among which gumma, tumor and gliomatosis must be particularly considered The colloidal gold tests are not definitely first zone and would usually be interpreted as negative With the other essentially negative results in the fluid, the probabilities lean toward the diagnoses suggested An ophthalmologic examination of the optic nerve heads would have been in order before this lumbar puncture was done in order to detect possible papillitis and choked disk, and the examiner was fortunate not to have lost the life of his patient through medullary block Localized pachymeningitic processes, brain gummas and vascular neurosyphilis are well known to give negative spinal fluids to lumbar puncture

The possible chain of events can only be guessed at in this case, but one wonders whether the single injection of arsphenamine several years before did not revive without subsequently suppressing a latent process in the nervous system with the appearance now of what might almost be regarded as a late neurorecurrent phenomenon In all cases, even a single injection of arsphenamine should be followed up by heavy metal therapy to prevent allergic and precocious tertiary manifestations.

Treatment in this case should not be begun or resumed with the arsphenamines. Instead, the patient should receive large doses of potassium iodide by mouth; and a soluble mercurial salt, such as mercuric succinimide, 0.016 Gm. (one-fourth grain), three or four times weekly, intramuscularly, will give a rapid and at the same time safe response probably free from therapeutic shock. After twenty such injections the patient may be shifted to a bismuth compound, and after one or even two courses of ten weekly injections each, a further discussion of therapeutic possibilities in the light of improvement would be in order.

It must not be forgotten that syphilis is only one of the possibilities that will explain a picture of this sort and that other evidence of brain tumor and the like may be expected and should be searched for if improvement under treatment for syphilis is not reasonably prompt.

MENSTRUAL HERPES OR DERMATITIS

To the Editor:—A woman, aged 24, a light blonde, suffers from a vesicular dermatitis of the forehead, which occurs about twelve days before menstruation and which persists until shortly after the termination of the period. Her facial skin, which is very oily, shows enlarged pores, which are more pronounced over the nose than elsewhere. There has been some slight constipation, of nervous origin, for several months, during which time the menstrual periods have often been delayed for several days. She is using Armand's face powder and Richard Hudnut's rouge. What treatment do you recommend for her skin? Please omit name.

M.D., Arizona.

Answer.—In 1912, Matzenauer and Polland (*Arch. f. Dermat. u. Syph.* **111**:385) described a series of cases under the title of dermatitis symmetrica dysmorrhoica. The publication of this article was followed by the appearance of five other articles in the German literature. The eruptions were characterized by symmetrical streaks and bands on various parts of the bodies of neurotic young women during the menstrual period. However, the reports were not convincing and the eruptions were probably self inflicted.

Catamenial herpes on the face, genitalia or buttocks occurs with almost every period in some women. The eruption tends to occur in approximately the same area with each subsequent attack. In arriving at a diagnosis it is necessary to determine whether the eruption is an erythematous and vesicular dermatitis or is herpetic. In the former there would be an area of more or less well defined erythema in which would be found vesicles of various sizes. The herpetic eruption would be characterized by a group of vesicopapules, or vesicles on a markedly inflamed base. The skin between the papules might appear normal. The dermatitis would be apt to run an irregular course and end by disappearance of the erythema and exfoliation of the ruptured vesicles, whereas the herpetic vesicles would run a fairly definite course, each lesion undergoing spontaneous involution.

There appears to be no reason why a cosmetic dermatitis should occur before the menstrual period.

Radiotherapy would be of much value, whether the eruption is due to irritants or to the virus of herpes.

ANTITOXIN IN ANTITUBERCLE BACILLUS SERUM

To the Editor:—I should like to know the usual technical method for finding correct antitoxin amounts in antibacillary serum (T. B.).

G. Elizondo Martel, M.D., Cienfuegos, Cuba.

Answer.—The presence of a true toxin in the tubercle bacillus or medium of its growth (i. e., a toxin analogous to diphtheria toxin, eliciting the production of antitoxin on injection into a suitable animal) has not been established. Therefore it is impossible to determine the amount of antitoxin in antitubercle bacillus serum.

ASTHMA IN PALESTINE

To the Editor:—Will you please inform me whether the air of Palestine is advantageous to an asthmatic patient (of the bronchitic type)? There is no evidence of any anaphylactic etiology.

Philip I. Levine, M.D., Brooklyn.

Answer.—We understand that in summer in Palestine there is not only the extreme heat but the frequent prevalence of strong winds carrying much dust and sand, which are exceedingly irritating in character. It is doubtful, therefore, whether a stay in Palestine would be of any particular advantage to a person with asthma.

OINTMENT BASE FOR VAPORIZER MIXTURE

To the Editor:—I should like to know what ointment base would be most suitable for use in a vaporizer, containing camphor, menthol, eucalyptol and turpentine, and the method of preparation. Please omit name.

M.D., Rhode Island.

Answer.—Petrolatum is a suitable base. The camphor and menthol (1 per cent of each) are triturated until liquefied, the eucalyptol or turpentine (3 per cent) is added, and the mixture is incorporated with the petrolatum.

Council on Medical Education and Hospitals

COMING EXAMINATIONS

American Board for Ophthalmic Examinations: Montreal, Sept. 19. Sec., Dr. William H. Wilder, 122 S. Michigan Ave., Chicago.

American Board of Obstetrics and Gynecology: The examination will be held in nineteen different cities in the United States and Canada, Oct. 22. Sec., Dr. Paul Titus, 1015 Highland Bldg., Pittsburgh.

American Board of Otolaryngology: Montreal, Sept. 17. Sec., Dr. W. P. Wherry, 1500 Medical Arts Bldg., Omaha.

Arizona: Phoenix, Oct. 3. Acting Sec., Dr. Jos. M. Greer, Professional Bldg., Phoenix.

California: *Reciprocity.* Los Angeles and San Francisco, Sept. 21. Sec., Dr. Charles B. Pinkham, 420 State Office Bldg., Sacramento.

Colorado: Denver, Oct. 4. Sec., Dr. William Whitridge Williams, 422 State Office Bldg., Denver.

Connecticut: *Basic Science.* New Haven, Oct. 8. Prerequisite to license examination. Address, State Board of Healing Arts, 1895 Yale Station, New Haven.

Idaho: Boise, Oct. 4. Dir., Bureau of License, Mr. F. L. Cruikshank, Boise.

Michigan: Lansing, Oct. 11-13. Sec., Dr. Nelson McLaughlin, 1010 Maccabee Bldg., Detroit.

Minnesota: *Basic Science.* Minneapolis, Oct. 4-5. Sec., Dr. J. Charnley McKinley, 126 Millard Hall, University of Minnesota, Minneapolis.

Montana: Helena, Oct. 4. Sec., Dr. S. A. Cooney, Power Block, Helena.

National Board of Medical Examiners: The examinations in Parts I and II will be held at all centers where there are five or more candidates available in a Class A medical school, Sept. 14-16. Ex. Sec., Mr. Everett S. Elwood, 225 S. 15th St., Philadelphia.

Nebraska: *Basic Science.* Lincoln, Oct. 4-5. Dir., Bureau of Examining Boards, Mrs. Clark Perkins, State House, Lincoln.

New Hampshire: Concord, Sept. 8-9. Sec., Dr. Charles Duncan, Concord.

New Mexico: Santa Fe, Oct. 10-11. Sec., Dr. P. G. Cornish, Jr., 221 W. Central Ave., Albuquerque.

New York: Albany, Buffalo, New York and Syracuse, Sept. 19-22. Chief, Professional Examinations Bureau, Mr. Herbert J. Hamilton, 315 State Education Bldg., Albany.

Oklahoma: Oklahoma City, Sept. 13-14. Sec., Dr. J. M. Byrum, Shawnee.

Porto Rico: San Juan, Sept. 6. Sec., Dr. O. Costa Mandry, Hospital Mimiya, Santurce, San Juan.

Wisconsin: *Reciprocity.* Milwaukee, Sept. 13. Sec., Dr. Robert E. Flynn, 315 State Bank Bldg., LaCrosse.

Wyoming: Cheyenne, Oct. 3. Sec., Dr. W. H. Hassed, Capitol Bldg., Cheyenne.

Minnesota June Report

Dr. E. J. Engberg, secretary, Minnesota State Board of Medical Examiners, reports the oral, written and practical examination held at Minneapolis, June 21-23, 1932. The examination covered 12 subjects and included 60 written questions. An average of 75 per cent was required to pass. Thirty-two candidates were examined, all of whom passed. Five physicians were licensed by reciprocity with other states. The following colleges were represented:

College PASSED	Year Grad	Per Cent
Northwestern University Medical School. (1930) 95.3,	(1932)	90.1
Rush Medical College	(1932)	90.2
Indiana University School of Medicine	(1932)	89.4
State University of Iowa College of Medicine	(1929)	94.3, (1930) 91.4, (1931) 89.4
Johns Hopkins University School of Medicine	(1932)	88.2
University of Michigan Medical School	(1929)	93.4
University of Minnesota Medical School	(1931)	91.6,* 92,* 92.5, 93.2, (1932) 86.2,* 89,* 89,* 89.1,* 89.4, 89.6,* 90.4,* 90.6, 91, 91.1,* 91.3, 91.5,* 91.6, 92.2, 92.3
Washington University School of Medicine	(1931)	88.3
University of Pennsylvania School of Medicine	(1929)	94.6
Marquette University School of Medicine	(1932)	88.5
University of Manitoba Faculty of Medicine	(1929)	91.5

College LICENSED BY RECIPROCITY	Year Grad	Reciprocity with
University of Illinois College of Medicine	(1928)	New York

John A. Creighton Medical College	(1916)	Montana
Jefferson Medical College of Philadelphia	(1927)	Michigan
University of Tübingen Faculty of Medicine	(1927)	New York

* These applicants have received their M.B. degree and will receive their M.D. degree on completion of an internship.

MEDICAL SOCIOLOGY IN THE MEDICAL SCHOOL CURRICULUM

JAMES PETER WARBASSE, M.D.
Woods Hole, Mass.

Our medical schools assume that the student admitted for medical education is already possessed of an adequate general culture. The schools rapidly engross the student in medical learning and proceed to carry him along in a transport of enthusiasm toward the goal of medical practice. He is, as it were, sequestered for four years from the rest of life and absorbed in the monastic seclusion of medicine.

This study in itself provides exceptional cultural value. Every man who pursues the course in medicine offered by our modern medical schools is bound to absorb a culture which is inherent in the pursuit of scientific knowledge. But the dominant purpose in the study of medicine is the perfecting of the medical technician; and it is to this end that the student addresses his energies.

In this age of the supremacy of commercialism, the medical student, as his studies approach the time when he must go out into the world and make his way, has to think of commercializing his knowledge. He wants a good medical education because it will win for him good economic rewards. This is natural and wise. The doctor must think about making money, because it is with money that he is going to surround himself with the best equipment and provide a home and the best advantages for his family. It is a notorious fact that, when the mind is fixed upon a means to attain an end, the means becomes the bright object of the desires, and the end often remains obscured in the clouds of misty uncertainty.

The competitive struggle into which the young practitioner is thrown is in a business world. Concern need not be felt so much for those men of fine quality who hold their calling in such esteem that the rewards of medical practice come naturally as a tribute to their superiority. But concern must be felt for that great mass of doctors who proceed to make their way by sheer business methods.

On every side, not only in the cities but in the country districts too, is heard the lament of the commercialization of medicine. No advantage can come from its denial. It is rampant and conspicuous. It is not wholly the fault of medicine or of medical education; it is inherent in the nature of the society in which we live. It is an evil, perhaps, less in evidence in the medical profession than in any of the other useful occupations —but it is in evidence, to our discredit.

Medicine is both an art and a business. But the shining art of medicine suffers eclipse by the dull routine of business. The medical schools are, perhaps, taking for granted too much of the cultural background of the students and expecting too much from the cultural virtue of the study of medicine itself. This virtue, unless well fortified, has some rude shocks awaiting it when it goes out into the world of business competition.

Is it not possible that in the medical school the students get an overdose of technological training and become surfeited with undiluted medicine, when their studies might profitably be sweetened with a subject that correlates all departments and broadens the view from the narrow picture of disease to the larger scene of all society?

Might not the medical school improve the quality of its graduates by adding to their training, as medical technicians, a medical culture aimed to impress the students with an understanding of medicine as an art and give to the doctor a broad social conception of his relation to humanity?

In a recent address, President Angell of Yale University spoke of the study of medical sociology as so useful that "it may be that we shall have to create one or more new chairs to deal with these problems" in our schools of medicine.

A few of our colleges have a chair of medical history. Many assign some member of the faculty to give a course of lectures on this subject. European universities have carried this branch of teaching further than we. But the value of medical history resides in its sociological implications. The best is not gotten out of the subject by presenting its bare facts, as names, dates, events and places. That was the method once employed in teaching geography, botany and anatomy. These are now made living subjects and linked with the other departments of learning and life. Medical history can be treated in the same way.

The Long Island College of Medicine, in New York, has established a required course with this object in view. It is to begin in the term of 1932-1933. Medical history is used simply as a scaffolding on which to erect a structure of the social relations of medicine. On this are built medical philosophy, medical ethics and medical economics, all parts of the larger façade of medical sociology. The medical history of all time is interpreted in its relation to the problems of present-day life and to the facts of medical practice. What has gone before in the development of the science of medicine illuminates the philosophical, ethical, and economic aspects of the medicine of today.

It is aimed to give the students a broader understanding of their art. The course includes a discussion of the biologic basis of medicine; medicine among lower animals; animal treatment of animal ills; medical aid as a natural accompaniment of the survival of species; the primitive healer, the priest, the medicine man, and witchcraft; the Aesculapian legend; the help of the gods; astrology and alchemy; the truths hidden in tradition, quackery and pseudoscience; facts sleeping in the lap of fiction; scientific curiosity; the power of tradition; health and morals; curiosity; expediency and bedside manners; the difference between law and medicine; humoral physiology, the precursor of the hormones; the hazards of wishful thinking; the philosophy of medicine.

Paracelsus illustrates bombastic medicine; Servetus, the conflict between science and tradition; Vesalius, the price of prosperity; Leeuwenhoek, the joy of seeing things never before seen; Paré, the doctor himself as the healing agent; Priestly and Dalton, exact observation; John Hunter, the relationship of all sciences; Jenner, utilitarian discoveries and their obligation to pure science; Corvisart, prestige and honesty; Simpson, overcoming intolerant opposition; Semmelweis, Pasteur and Lister, the great benefactions; Koch, how to know a fact; Osler, the exemplification of medical culture. These subjects give some idea of the interpretive possibilities of this course.

Connected with the historical background of medicine are the salient affairs of the doctor's life today. These call for discussion of medicine as a social science; the sick cell, the sick man, the sick society; the doctor as philanthropist; quackery, secrets and patents disavowed; the rewards and compensations of medicine; the meaning of success.

Finally, the physician perfecting himself in order to attain the great satisfactions; the physician's duty to himself; medicine as an art, science, profession and business; the unity of doctors; the medical guild; the medical society; the doctor's contacts with the community—individual competition, group experts, state medicine, guild statism, consumers' cooperation—their advantages and disadvantages; what is happening to the medical profession in the absence of its own planning to meet the exigencies of a radically changing society; a plan of medical organization adapted to the needs of the doctors and the times; preserving the doctor as a free individual in a mechanized age.

These are hints of the possibilities of a course of instruction on medical sociology for medical students, based on the history of medicine. Such a course, interspersed in the midst of the strenuous grind of education, may mellow and mollify the acerbities of technical training and help the doctor to view his profession as an art. It is possible that such a course may prepare the physician to live in better harmony with his colleagues, to serve more efficiently the society in which he lives, to be a more effective doctor, and finally to find greater satisfactions in the practice of his profession.

Neoplasms of Domesticated Animals By William H Feldman, D V M, M S, Division of Experimental Surgery and Pathology, the Mayo Foundation, Rochester Minnesota With a foreword by Charles H Mayo, M D Mayo Clinic Monographs Cloth Price, $6 Pp 410 with 193 illustrations Philadelphia and London W B Saunders Company, 1932

The study of animal tumors has assumed great importance in recent years owing to the demonstration of the transmissibility of the malignant neoplasms occurring spontaneously in albino mice and rats Of late, the discovery of a peculiar sarcoma of the fowl has interested investigators on tumors because this growth is transmissible by cell-free filtrates This property has been used as a basis for far reaching but as yet unsubstantiated theories concerning the possibility of a parasitic origin of human growths However, this property of filtrability seems to be wholly confined to tumors of the fowl Interesting tumors in guinea-pigs and rabbits are also being studied Such investigation has led to renewed interest in the morphologic examination of the great variety of neoplasms frequently found in other domesticated animals, and it is now clear that practically all the tumors that occur in human beings may be found in animals Most of the information on the subject, with the exception of the well known volume by Woglom on experimental cancer, published in 1913, has been either in a foreign language or in veterinary journals not readily accessible to the physician This collection of nearly all that is known concerning natural history of animal tumors is therefore of great value The illustrations are reproductions of photographs of gross material and photomicrographs of the histologic details of the neoplasms Each chapter is followed by an ample and accurate bibliography, and there is a competent section on methods of preservation of pathologic material For those who are working with animal tumors it is an invaluable source book and should be in every pathologic laboratory

A Text-Book of Surgical Pathology By Charles F W Illingworth M D, F R C S, and Bruce M Dick Cloth Pp 677 with 290 illustrations London J & A Churchill 1932

The evaluation of this book offers certain difficulties If its purpose is to supply a purely practical and relatively elementary outline in surgical pathology, as indeed it would appear from the preface, its object is well attained, if it is to offer an insight into the more fundamental problems that face the surgeon—inflammation, wound healing, resistance, tissue dysfunction, the state of the circulation—the book is of little value Organ pathology is presented in twenty-six well written, well illustrated and properly balanced chapters As such it reflects the point of view of the surgeon as a mechanist and of the pathologist who seeks to confine his interests to that level Surgery today has advanced far beyond this simple concept, though there is little to indicate this in the text The little that is offered seems superficial and haphazard Thus the book opens with three pages on surgical shock, two on burns, nine on tuberculosis Then follow four on actinomycosis, four on gas gangrene (the heading is "aerogenic infection" obviously a misnomer) and nine of echinococcus disease The array is rather motley and of totally unequal value whether from the practical or from the scientific point of view It might reasonably be supposed that the subject of inflammation would deserve some consideration, but of this there is no mention Obviously the book has its limitations

Technique de l'ostéosynthese Étude de quelques procédés Par Robert Danis professeur de clinique chirurgicale à l Universite de Bruxelles Paper Price 55 francs Pp 161 with 149 illustrations Paris Masson & Cie 1932

This book is presented largely from the author's laboratory and clinical experience A number of rules to be followed in performing a successful operation on fractures are given and emphasis is placed on unnecessary freeing of the fragments Immobilization after operation is stressed, especially when a foreign body has been used A rather complicated but apparently useful operating table has been devised for various operations on the extremities and also for holding the patient in difficult positions for other operations A number of instruments are described for holding bone fragments and for inserting and tightening wire sutures The author is enthusiastic regarding the use of multiple wire sutures for the fixation of bone fragments He describes numerous plans for wiring the ends of fractured bones A few typical cases are reported, but infection, which developed about the wires in a number of these, necessitated their removal Occasionally bone infection occurred but the result eventually seemed to be good In badly comminuted fractures the author uses a special wire screen wrapped and reenforced with wire around the fragments The method of making and the use of an autogenous bone graft and bone screws for fixation are described The graft is cut from the crest of the tibia but is rarely used except in bridging a defect or in a severe pseudarthrosis Early use of the extremities is hastened by the support of a specially made celluloid splint laced up on one side so that it may be tightened as necessary The necessity for open operation on certain fractures difficult to reduce and maintain is well known, but the frequent use of multiple perforating wire sutures and a large amount of foreign material can scarcely be sanctioned In general, screws or even plates are less likely to infection and certainly far easier to remove Osteomyelitis resulting from perforating wire sutures is particularly difficult to cure, and the wire itself is often difficult to remove The book may be read for its original suggestions in the technic of application of wire sutures and screws

Strahlenbehandlung bei Hautkrankheiten· Licht, Radium, Röntgen- und Grenzstrahlen Ein Lehrbuch für Studierende und Ärzte Von Dr Franz Blumenthal, a o Professor an der Universität stellvertr Direktor der Universitats Hautklinik in Berlin und Dr Lothar Bohmer, Assistent der Hautklinik in Berlin Second edition Paper Price 15 marks Pp 274 with 128 illustrations Berlin S Karger, 1932

Since the first edition of this manual appeared in 1924 there have been many constructive developments in radiation therapy The biology and physics of light, radium, roentgen rays and grenz rays are discussed in a thoroughly scientific manner, with appropriate illustrations of the various modalities in modern usage The important subject of dosage, both qualitative and quantitative, is adequately covered In the biologic-clinical section the changes produced in the skin by irradiation are discussed in addition to the technic of treatment as applied to different dermatologic disorders in the light institute of the Berlin University skin clinic The authors are to be congratulated on having condensed a large amount of valuable material into a small volume that will be of great interest to dermatologists and radiation therapists

Tuberculose osseuse et ostéo-articulaire Par Etienne Sorrel chirurgien de l Hôpital Trousseau et Mme Sorrel Dejerine Fascicules I et II Cloth Price 380 francs Pp 514, with 640 illustrations Paris Masson & Cie, 1932

These atlases on bone and joint tuberculosis were written by Sorrel and his wife The books constitute a summary of lectures that have been given twice each year during Sorrel's long residence at the Maritime Hospital at Berck to French and foreign physicians Chapter I includes tuberculous osteitis as it occurs in the large and small long bones, and in the short and flat bones, chapter II includes or discusses tuberculous ostearthritis of the upper extremities, viz, the wrist, elbow and shoulder of the child and adult, chapter III, tuberculous ostearthritis of the lower extremities and the sacro-iliac joints, and chapter IV, tuberculous ostearthritis of the spinal column There is a discussion of Pott's disease as it occurs in the child and the adult and infection of the posterior portions of the vertebrae, viz, the posterior arch, spinous process, transverse process and vertebral articulations The author's views on the treatment of Pott's paraplegia are well known The illustrations include roentgenograms, line drawings and diagrams of operations These include the operative treatment of spina ventosa, resection of the wrist, elbow, shoulder and mediotarsal joint, astragalectomy, resection of the knee and the hip, the technic of extra-articular arthrodesis of the hip, the Albee spine operation, the osteoperiosteal graft and the Hibbs operation Especially noteworthy are the illustrations of amputations, astragalectomy and sequestrectomy by Frantz There are instructive diagrams of the pathologic anatomy of tuberculosis of the knee and hip The work of the publishers is good These books should be looked over, even if not read, by evey orthopedic surgeon and roentgenologist

Die Anamnese. Psychologie und Praxis der Krankenbefragung. Von Prof. Dr. Georg Grund, Direktor der Medizinischen Univ.-Poliklinik in Halle a. S. Boards. Price, 12 marks. Pp. 242. Leipzig: Johann Ambrosius Barth, 1932.

This book is much more than a simple manual of history taking. It is introduced by the author with the statement that the art of taking a medical history, which is more difficult to learn than most methods of investigation of the patient, has lost ground with the introduction of so many new methods of examination, and he makes a plea for recognition of its true worth and importance and for proper emphasis on it in both the teaching and the practice of medicine. The author attributes the common neglect of the teaching of history taking in part at least to the fact that there has never been an adequate compilation of current knowledge on this subject, and this book represents his attempt to fill what he regards as a real need. After an introduction which covers the general principles and psychology of history taking the book is divided into two main parts, the history being regarded from the standpoint of symptoms and from the standpoint of etiology. The general method followed is that of describing such symptoms as are related by or as may be elicited from the patient, and of pointing out the possible connection of the patient's story with pathologic changes. This method is used successfully, and the exposition is exhaustive, clear and concise. A similar method is used in the review of the history from the standpoint of etiology. There is a chapter on the elucidation of psychogenic factors in the etiology of the organic manifestations of disease, and in discussing symptoms as related by the patient attention is constantly called to the possibility of their psychic origin. The book would perhaps have been strengthened by a section devoted specifically to the neuroses, both on account of their importance in producing symptoms and on account of the importance of the history in making the diagnosis of neurosis. On the whole, the book is well worth while for any physician who wishes further to cultivate the art of history taking in himself or in his pupils, and it should serve a useful purpose in redirecting attention to what may be in some danger of becoming a lost art.

La Escuela Médica Peruana: Por los senderos de Unánue. Por Prof. C. E. Paz Soldan. Biblioteca del Centenario de Hipólito Unánue. Paper. Pp. 186. Lima: Le Reforma Médica, 1932.

This anniversay volume, a tribute to Hipólito Unánue, founder of the country's first medical school, deals with the past, present and future of medical education in Peru. The first section, which is of greatest interest, unfolds the panorama of the development of medical practice during the colonial era, and especially the establishment of hospitals as charitable institutions. The heroic efforts of Unánue at the beginning of the nineteenth century are vividly portrayed. Then follows a cursory description of the vicissitudes political, economic and educational, culminating in the merger with the University of San Marcos. The second section deals with the "convulsive" decade, 1919-1929, when the students were in revolt and all the activities of higher education were in abeyance. After discussing the causes of the recent débâcle the author takes up the problems of the future, expounding a neat and logical plan of organization and reglementation. To those interested in the educational developments "below the line," the book will prove a valuable guide.

Lectures on Psychiatry. By E. D. Wiersma, M.D., Professor of Psychiatry and Neurology, Groningen. Cloth. Price, 25/-. Pp. 610, with 143 illustrations. London: H. K. Lewis & Company, Ltd., 1932.

As the author states in his preface, the lectures on psychiatry are theoretical lectures. The individual mental diseases and their etiology, prognosis and therapeutics are touched on either not at all or only incidentally. The lectures are to a great extent studies in psychopathology and were delivered at the University at Groningen, where Dr. Wiersma occupied the chair of neurology and psychiatry for more than thirty years. Believing that neurology and psychiatry are two closely related subjects, the author is not in favor of having these subjects taught by different teachers. He fears that such a division of the two subjects may give a too one-sided development toward the neurologic or psychiatric side. With only a passing review of the teachings of Freud, Adler and Young, the organic basis of abnormal mental reactions is studied in extenso. In chapter I the intimate connection between the phenomena of consciousness and material processes is pointed out. In chapter IV a study of the relationship between bodily build of the races and constitution types to a given psychic structure is made. "A presumption is justified" that from the shape of the body a function appropriate to it may be predicted. Chapters V, VI, VII, VIII and IX are given to the study of consciousness, degrees and extent of consciousness and its determination. An excellent study of memory disturbances, disturbances in thinking and dementia is given in chapters XII, XIII, XIV and XV. In chapter XIX, under the caption of "Manifestations of the Will" a detailed psychologic interpretation of reflexes is made. An agreement is found between conscious manifestation of the will and reflexes as it is seen in the correspondence between reaction time and reflex time. Automatisms and instinctive and impulsive actions are elucidated. In the last chapter, apraxias, aphasias and dysarthrias are discussed as manifestations of volitional disturbances.

Contribution à l'étude du traitement des fractures ouvertes de jambe. Par le Dr. Louis Darfeuille. Paper. Pp. 170, with illustrations. Paris: Librairie Arnette, 1932.

The authors state that, according to the statistics, all methods have given variable results. Closed synthesis, although having a 1.7 per cent mortality and favorable results in 80 per cent of the cases, cannot be regarded as the treatment of choice in all cases of compound fractures. There is, however, no uniform or universal treatment of fracture of the lower leg. Of the various types of technic from which the surgeon may choose, he must be guided in the individual case by the degree of anatomic displacement and the time that has elapsed since the accident.

The History of Taste: An Account of the Revolutions of Art Criticism and Theory in Europe. By Frank P. Chambers. Cloth. Price, $4.25. Pp. 342, with 12 illustrations. New York: Columbia University Press, 1932.

The author consulted medieval writers for their views and opinions on architecture, sculpture and painting executed in their own time and then traced the changes during the Renaissance through the period of the romantic movement and the revivals of the last century. Apparently the views of mankind change greatly under various circumstances and among various peoples. The author is convinced that there is a kind of destiny in taste—a cycle as it were—which no man controls and in which some deeper historical significance may be sought. The volume is magnificently printed and beautifully illustrated and might well form a model for publishers of other semiscientific workers.

Fleckfieber und Nervensystem. Von Dr. Nikolai Hirschberg. Sonderausgabe von Heft 66 der „Abhandlungen aus der Neurologie, Psychiatrie, Psychologie und ihren Grenzgebieten." Paper. Price, 11.60 marks. Pp. 124. Berlin: S. Karger, 1932.

In typhus fever the nervous system is affected with remarkable regularity. Though it causes also a number of somatic disturbances, these are neither clinically nor pathologically so prominent and important as the nervous complications. It also gives rise to a number of curable, transient psychoses and therefore is remarkable also for the absence of sequelae which are so common after another infection of the central nervous system known as epidemic (lethargic) encephalitis. Rare and practically unknown in this country, typhus fever is prevalent in Europe. During the Great War it swept over Russia, Poland (epidemic of 1918-1919), some provinces of the former, Austria and the Balkan countries and the military camps of the warring nations. An enormous opportunity presented itself to clinicians and research workers to study the disease from various angles. Their vast experience has been faithfully recorded by Hirschberg, who devotes 13 pages to pathology and the rest of the book to the clinical features and the bibliography of 275 articles. The nerve lesions are covered minutely. The peripheral nerves, sympathetic nervous system, spinal cord and various parts of the brain are taken up separately. As there is hardly a portion of the central nervous system that is not involved in this disease, the monograph is a short but lucid review of the most interesting phases of neurology, including, for instance, the chapters on the extra-

Book Notices

Neoplasms of Domesticated Animals. By William H. Feldman, D.V.M., M.S., Division of Experimental Surgery and Pathology, the Mayo Foundation, Rochester, Minnesota. With a foreword by Charles H. Mayo, M.D. Mayo Clinic Monographs. Cloth. Price, $6. Pp. 410, with 193 illustrations. Philadelphia and London: W. B. Saunders Company, 1932.

The study of animal tumors has assumed great importance in recent years owing to the demonstration of the transmissibility of the malignant neoplasms occurring spontaneously in albino mice and rats. Of late, the discovery of a peculiar sarcoma of the fowl has interested investigators on tumors because this growth is transmissible by cell-free filtrates. This property has been used as a basis for far reaching but as yet unsubstantiated theories concerning the possibility of a parasitic origin of human growths. However, this property of filtrability seems to be wholly confined to tumors of the fowl. Interesting tumors in guinea-pigs and rabbits are also being studied. Such investigation has led to renewed interest in the morphologic examination of the great variety of neoplasms frequently found in other domesticated animals, and it is now clear that practically all the tumors that occur in human beings may be found in animals. Most of the information on the subject, with the exception of the well known volume by Woglom on experimental cancer, published in 1913, has been either in a foreign language or in veterinary journals not readily accessible to the physician. This collection of nearly all that is known concerning natural history of animal tumors is therefore of great value. The illustrations are reproductions of photographs of gross material and photomicrographs of the histologic details of the neoplasms. Each chapter is followed by an ample and accurate bibliography, and there is a competent section on methods of preservation of pathologic material. For those who are working with animal tumors it is an invaluable source book and should be in every pathologic laboratory.

A Text-Book of Surgical Pathology. By Charles F. W. Illingworth, M.D., F.R.C.S., and Bruce M. Dick. Cloth. Pp. 677, with 290 illustrations. London: J. & A. Churchill, 1932.

The evaluation of this book offers certain difficulties. If its purpose is to supply a purely practical and relatively elementary outline in surgical pathology, as indeed it would appear from the preface, its object is well attained; if it is to offer an insight into the more fundamental problems that face the surgeon—inflammation, wound healing, resistance, tissue dysfunction, the state of the circulation—the book is of little value. Organ pathology is presented in twenty-six well written, well illustrated and properly balanced chapters. As such it reflects the point of view of the surgeon as a mechanist and of the pathologist who seeks to confine his interests to that level. Surgery today has advanced far beyond this simple concept, though there is little to indicate this in the text. The little that is offered seems superficial and haphazard. Thus the book opens with three pages on surgical shock, two on burns, nine on tuberculosis. Then follow four on actinomycosis, four on gas gangrene (the heading is "aerogenic infection" obviously a misnomer) and nine of echinococcus disease. The array is rather motley and of totally unequal value whether from the practical or from the scientific point of view. It might reasonably be supposed that the subject of inflammation would deserve some consideration, but of this there is no mention. Obviously the book has its limitations.

Technique de l'ostéosynthèse: Étude de quelques procédés. Par Robert Danis, professeur de clinique chirurgicale à l'Université de Bruxelles. Paper. Price, 55 francs. Pp. 161, with 149 illustrations. Paris: Masson & Cie, 1932.

This book is presented largely from the author's laboratory and clinical experience. A number of rules to be followed in performing a successful operation on fractures are given and emphasis is placed on unnecessary freeing of the fragments. Immobilization after operation is stressed, especially when a foreign body has been used. A rather complicated but apparently useful operating table has been devised for various operations on the extremities and also for holding the patient in difficult positions for other operations. A number of instruments are described for holding bone fragments and for inserting and tightening wire sutures. The author is enthusiastic regarding the use of multiple wire sutures for the fixation of bone fragments. He describes numerous plans for wiring the ends of fractured bones. A few typical cases are reported, but infection, which developed about the wires in a number of these, necessitated their removal. Occasionally bone infection occurred but the result eventually seemed to be good. In badly comminuted fractures the author uses a special wire screen wrapped and reenforced with wire around the fragments. The method of making and the use of an autogenous bone graft and bone screws for fixation are described. The graft is cut from the crest of the tibia but is rarely used except in bridging a defect or in a severe pseudarthrosis. Early use of the extremities is hastened by the support of a specially made celluloid splint laced up on one side so that it may be tightened as necessary. The necessity for open operation on certain fractures difficult to reduce and maintain is well known, but the frequent use of multiple perforating wire sutures and a large amount of foreign material can scarcely be sanctioned. In general, screws or even plates are less likely to infection and certainly far easier to remove. Osteomyelitis resulting from perforating wire sutures is particularly difficult to cure, and the wire itself is often difficult to remove. The book may be read for its original suggestions in the technic of application of wire sutures and screws.

Strahlenbehandlung bei Hautkrankheiten: Licht, Radium, Röntgen- und Grenzstrahlen. Ein Lehrbuch für Studierende und Ärzte. Von Dr. Franz Blumenthal, a. o. Professor an der Universität, stellvertr. Direktor der Universitäts-Hautklinik in Berlin, und Dr. Lothar Böhmer, Assistent der Hautklinik in Berlin. Second edition. Paper. Price 15 marks. Pp. 274, with 128 illustrations. Berlin: S. Karger, 1932.

Since the first edition of this manual appeared in 1924 there have been many constructive developments in radiation therapy. The biology and physics of light, radium, roentgen rays and grenz rays are discussed in a thoroughly scientific manner, with appropriate illustrations of the various modalities in modern usage. The important subject of dosage, both qualitative and quantitative, is adequately covered. In the biologic-clinical section the changes produced in the skin by irradiation are discussed in addition to the technic of treatment as applied to different dermatologic disorders in the light institute of the Berlin University skin clinic. The authors are to be congratulated on having condensed a large amount of valuable material into a small volume that will be of great interest to dermatologists and radiation therapists.

Tuberculose osseuse et ostéo-articulaire. Par Etienne Sorrel, chirurgien de l'Hôpital Trousseau, et Mme. Sorrel-Dejerine. Fascicules I et II. Cloth. Price, 380 francs. Pp. 514, with 640 illustrations. Paris: Masson & Cie, 1932.

These atlases on bone and joint tuberculosis were written by Sorrel and his wife. The books constitute a summary of lectures that have been given twice each year during Sorrel's long residence at the Maritime Hospital at Berck to French and foreign physicians. Chapter I includes tuberculous osteitis as it occurs in the large and small long bones, and in the short and flat bones; chapter II includes or discusses tuberculous ostearthritis of the upper extremities; viz., the wrist, elbow and shoulder of the child and adult; chapter III, tuberculous ostearthritis of the lower extremities and the sacro-iliac joints, and chapter IV, tuberculous ostearthritis of the spinal column. There is a discussion of Pott's disease as it occurs in the child and the adult and infection of the posterior portions of the vertebrae; viz., the posterior arch, spinous process, transverse process and vertebral articulations. The author's views on the treatment of Pott's paraplegia are well known. The illustrations include roentgenograms, line drawings and diagrams of operations. These include the operative treatment of spina ventosa, resection of the wrist, elbow, shoulder and mediotarsal joint, astragalectomy, resection of the knee and the hip, the technic of extra-articular arthrodesis of the hip, the Albee spine operation, the osteoperiosteal graft and the Hibbs operation. Especially noteworthy are the illustrations of amputations, astragalectomy and sequestrectomy by Frantz. There are instructive diagrams of the pathologic anatomy of tuberculosis of the knee and hip. The work of the publishers is good. These books should be looked over, even if not read, by evey orthopedic surgeon and roentgenologist.

Die Anamnese. Psychologie und Praxis der Krankenbefragung. Von Prof. Dr. Georg Grund, Direktor der Medizinischen Univ.-Poliklinik in Halle a. S. Boards. Price, 12 marks. Pp. 242. Leipzig: Johann Ambrosius Barth, 1932.

This book is much more than a simple manual of history taking. Fleckfieber und Nervensystem. Von Dr. Nikolai Hirschberg. Sonderausgabe von Heft 66 der „Abhandlungen aus der Neurologie, Psychiatrie, Psychologie und ihren Grenzgebieten." Paper. Price, 11.60 marks. Pp. 124. Berlin: S. Karger, 1932.

In typhus fever the nervous system is affected with remarkable regularity. Though it causes also a number of somatic disturbances, these are neither clinically nor pathologically so prominent and important as the nervous complications. It also gives rise to a number of curable, transient psychoses and therefore is remarkable also for the absence of sequelae which are so common after another infection of the central nervous system known as epidemic (lethargic) encephalitis. Rare and practically unknown in this country, typhus fever is prevalent in Europe. During the Great War it swept over Russia, Poland (epidemic of 1918-1919), some provinces of the former, Austria and the Balkan countries and the military camps of the warring nations. An enormous opportunity presented itself to clinicians and research workers to study the disease from various angles. Their vast experience has been faithfully recorded by Hirschberg, who devotes 13 pages to pathology and the rest of the book to the clinical features and the bibliography of 275 articles. The nerve lesions are covered minutely. The peripheral nerves, sympathetic nervous system, spinal cord and various parts of the brain are taken up separately. As there is hardly a portion of the central nervous system that is not involved in this disease, the monograph is a short but lucid review of the most interesting phases of neurology, including, for instance, the chapters on the extra-pyramidal system and the rôle of the sympathetic system in the causation of various cerebral disorders. It is of additional value because of the rich personal experience of the author and the liberal references to the Russian literature, valuable but hardly accessible.

La créatininémie. Par Dr. Maurice Dérot. Paper. Pp. 238. Paris: Librairie Médicale Marcel Vigné, 1932.

Dérot reports studies on the creatinine concentration of serum on patients and experimental animals. He used Folin's method and found creatinine elevated in acute and chronic nephritis and other disease associated with renal lesions. In dogs and rabbits, elevated serum creatinine was brought about by nephritis produced by bismuth, mercuric chloride, and diphtheria toxin, as well as bilateral ligation of the ureters or bilateral nephrectomy. He feels that creatinine determinations are of definite help in nephritis but should be used in conjunction with urea determinations. The book contains little new. The author mentions, but does not answer, the objections to the Jaffé reaction and assumes that the error is of no clinical importance.

The Mongol in Our Midst: A Study of Man and His Three Faces. By F. G. Crookshank, M.D., F.R.C.P. Third edition. Cloth. Price, 21s Pp. 539, with illustrations. London: Kegan Paul, Trench, Trubner & Company, Ltd., 1931.

This is the third edition of a volume which attracted wide attention when it first became available. Dr. Crookshank is not so much concerned with the imbecile mongoloid as with nonracial mongolism. He comes to no definite conclusion as to the significance of the mongol but he does say that if we could finally discover the real cause for the presence of mongolism in our midst we should know not merely what God and man are but how they both came to be. In reaching this conclusion he traces all the views of evolution of man that have held public interest since the darwinian view first startled the world.

Miscellany

TAXING ANTIVIVISECTION BEQUESTS

Following is an opinion of the United States Board of Tax Appeals in the case of the Pennsylvania Company for Insurances on Lives and Granting of Annuities versus the Commissioner of Internal Revenue, promulgated, April 18:

The respondent has proposed an additional assessment of estate tax in the amount of $17,657.56. The only issue is whether a bequest to the American Anti-Vivisection Society of Philadelphia is exempt from estate tax under the provisions of section 303 (a) (3) of the Revenue Act of 1924. The parties have entered into certain stipulations which the board accepts and incorporates in this report by reference.

So far as pertinent to this proceeding, section 303 (a) (3), which governs the issue here, is as follows:

> For the purpose of the tax the value of the net estate shall be *determined*—
>
> (a) In the case of a resident, by deducting from the value of the gross estate . . .
>
> (3) The amount of all bequests . . . to or for the use of any corporation organized and operated exclusively for . . . the prevention of cruelty to . . . animals . . ."—*Revenue Act of 1924.*

The *Commissioner's regulation for the administration of the* above provision in Regulations 68 (1924) is as follows:

> *Religious, charitable, scientific, and educational corporations.* A corporation or association to which such a bequest was made must meet three tests: (1) It must be organized and operated for one or more of the specified purposes; (2) it must be organized and operated exclusively for such purpose or purposes; and (3) no part of its net earnings shall insure to the benefit of private stockholders or individuals.—*Regulations 68 (1924 Ed.)*

The American Anti-Vivisection Society is a Pennsylvania corporation chartered May 1, 1883. Its purposes as set out in the original character were to restrict the practice of vivisection within proper bounds and to prevent the injudicious and needless infliction of suffering on animals under the pretense of scientific and medical research. On May 23, 1885, the charter was amended by changing the name of the corporation to American Society for the Restriction of Vivisection. On May 15, 1889, it was again amended to declare the purpose of the society to be "the total abolition of all vivisectional experiments on animals and other experiments of a painful nature" and the name was changed to American Anti-Vivisection Society.

The American Anti-Vivisection Society engages in various activities to effect the purposes for which it was organized. It gives rent free use of certain rooms to the Animal Rescue League and contributes to the expense of that organization, which takes off the streets of Philadelphia animals that in some cases might find their way into vivisectional laboratories. It provides for free lectures and uses billboard advertising space in its propaganda work against vivisection. It publishes a monthly magazine in which there are always some articles on the cruelty of vivisectional experiments. It has kept a man near the laboratories of the University of Pennsylvania to learn whether stolen dogs were delivered to the kennels of that institution and has sent notices to owners advising them to look out not only in the city pound but in the vivisectional laboratory for missing animals.

Vivisectional experiments are conducted in various research laboratories maintained by publicly supported and/or privately endowed medical schools and endowed foundations throughout the world. The Rockefeller Institution, a research foundation engaged in investigating the causes and cures of human diseases, especially cancer, maintains its own vivisection laboratory. Similar work is done in the medical and biological departments of many of the great universities, such as Johns Hopkins of Baltimore, Pennsylvania of Philadelphia and many others throughout the country.

Under the laws of most of our states and of many countries, cruelty to animals is an indictable offense, subject on conviction to heavy penalties. Societies to assist the authorities in the enforcement of such laws have been established in many jurisdictions. Such organizations have done much to relieve animals from needless suffering inflicted by careless or cruel owners and others. Recognizing the social value of such work, Congress included the exemption provision here relied on in the Revenue Act of 1924. It has been held, however, that legislation to prevent cruelty to animals is not based on consideration for animals or recognition of man's obligation to treat them decently, but on the theory that such cruelty is "an offense against public morals which the commission of cruel and barbarous acts tends to corrupt." *Commonwealth* v. *Turner,* 145 Mass. 296; 14 N. E. 130.

The courts have had many occasions to discuss and define cruelty, but our research fails to disclose any material variation from Webster's definition, that it is "disposition to give unnecessary pain or suffering to others; inhumanity, barbarity; . . . inhuman treatment; act of wilfully causing unnecessary pain." In conformity with this definition the courts have very generally held that cruelty in a legal sense is wilful, wanton and unnecessary infliction of pain. It is cruel to let loose a captive fox to be harried by hounds for gratification of human spectators, *Commonwealth* v. *Turner, supra,* or to kill or maim live pigeons that have been kept in captivity. *Waters* v. *People,* 23 Colo. 33; 46 Pac. 112. Cf. *State* v. *Porter,* 112 N. C. 887; 16S. E. 915. On the other hand, the same courts have held that the statutes against cruelty to animals should not be construed to prevent killing game in its wild state.

The domestic use of animals requires many painful operations, none of which have ever been forbidden by legislation or denounced by the courts as cruel acts. Dehorning domestic animals inflicts great suffering; but it is not only tolerated but is very generally practiced and, in Pennsylvania, it has the sanction of the legislature and the courts. Act. Pa. 1895, from 25 P. L. 286. Breaking, branding, marking, punishing, working, docking, castrating, spaying and caponizing are ordinary incidents in keeping animals to supply food or render service to man. Such operations must cause intense pain and suffering and certainly are not for the benefit of the animals but they have never been legally outlawed or even stigmatized as cruel, inhuman or barbarous by legislation or judicial decisions. Usage and law tolerate, permit and even encourage, and in some instances require such operations with the single limitation, not always too strictly observed, that they must be done with a minimum of suffering for the helpless creatures dedicated by age old custom to man's necessities.

Within the meaning of the law every living creature, except man, is an animal and all are either the friends or foes of human beings. Throughout all history it has been necessary and therefor laudable to exterminate the animal enemies of humanity. Snares, traps, arrows, guns, poison, fire, parasites and countless other lethal agents and deadly devices have been used to protect man, his health and property from the menaces and depredations of noxious beasts, birds, reptiles and insects. For this purpose killers have been subsidized by the nations and the states and all the agencies of science have been enlisted. Municipalities vote bounties to encourage this warfare. Even the Congress appropriates the revenues for the extirpation of weevils, grasshoppers, fruit flies and other pests that threaten the prosperity and well being of the people. Without question this never ending conflict between man and the so-called lower forms of life has caused dreadful pain and suffering to countless sentient beings; but man's necessity knows no higher law than self preservation and must be served.

The prevention and cure of human diseases are only other phases of man's struggle to survive and are no less necessary than the conquest of visible and powerful enemies. From the dawn of history until within the very recent past, mankind has been ravaged by epidemics of contagious and infectious plagues. The migrating pests of the early and middle ages, Asiatic cholera, yellow fever, syphilis and smallpox destroyed millions of lives and impoverished whole countries of happiness and prosperity before they were vanquished by dauntless men who gave their time, talent and, in many instances, their own lives to human service in the laboratories of the scientific world. Vivisection has long been considered a vitally essential investigative method in physiology, pathology, biology and curative medicine and surgery. Cerebrospinal meningitis, long regarded as practically incurable, has been conquered by an antitoxin discovered in the vivisectional laboratories of the Rockefeller Foundation and has reduced the mortality of that scourge from more than 75 to less than 25 per cent. In the experimentation which developed that antitoxin, 100 guinea-pigs and 25 monkeys were sacrified to human necessity, but for each monkey or pig so used there are today scores of sound human beings who have been restored to health and the service of their families and society by the necessary use of lower animals in the interest of mankind.

Following the discovery of America and for more than 400 years, syphilis and its sequalae in many forms ravaged the nations of the western world. This scourge, so contagious and insidious that it baffled medical science and caused untold suffering and shame to innocent and guilty alike, has been conquered within our own generation by the scientist Ehrlich, who discovered his famous specific after seven years of vivisectional experimentation and the trial and rejection of more than 700 alleged remedies. Space forbids more than the mention of similar results in the prevention and treatment of diphtheria, hydrophobia, tuberculosis, typhoid, and many other diseases that have yielded, or are yielding, to the attacks of science. The results already attained promise much for the future. Cancer, said to kill one person of every eight who dies after the age of 40, remains unconquered. If its germ is ever identified, and its cure determined, the vivisectional laboratories must, in all probability, render that service to humanity.

Experimentation on living animals in the interest of medical progress has been endorsed with singular unanimity by learned societies and associations devoted to the curative arts and the advancement of science. On Aug. 12, 1913, the International Medical Congress, composed of distinguished members of the profession from every civilized country in the world, without a dissenting vote approved the following resolution:

> That this Congress records its conviction that experiments on living animals have proved of the utmost service to medicine and are indispensable to the future progress. That, accordingly, while strongly deprecating the infliction of unnecessary pain, it is the opinion, alike in the interest of man and animals, that it is not desirable to restrict competent persons in the performance of such experiments.

To the like effect are resolutions adopted by the British Medical Association in 1892, and the American Medical Association and the American Association for the Advancement of Science in 1908. These resolutions represent the collective opinion of the medical profession of all countries. On the other hand, extensive research has failed to disclose a single adverse resolution of any scientific body.

For more than two generations, vivisectional experiments have had the unqualified endorsement of the most distinguished investigators. In a letter written April 14, 1881, Charles Darwin said:

> On the other hand I know that physiology can make no progress if experiments on living animals are suppressed and I have an intimate conviction that to retard the progress of physiology is to commit a crime against humanity. . . . Unless one is absolutely ignorant of all that science has done for humanity, one must be convinced that physiology is destined to render incalculable benefits to man and even to animals. See the results obtained by M. Pasteur's work on the germ of contagious diseases; will not animals be the first to profit thereby? How many lives have been saved, how much suffering spared by the discovery of parasitic worms following the experiments made by Virchow and others on living animals!

As far back as 1863, Claude Bernard, one of the greatest scientists of that day, wrote:

> You ask me what are the principal discoveries due to vivisection. . . . All the knowledge possessed by experimental physiology can be quoted in that connection; there is not a single fact which is not the direct and necessary consequence of vivisection. From Galen, who, by cutting the laryngeal nerves, learnt their use for respiration and the voice to Harvey, who discovered circulation; Pecquet and Aselli, the lymphatic vessels; Bell and Magendie the nervous function, and all that has been learned since the extension of that method of vivisection, which is the only experimental method; in biology, all that is known on digestion, circulation, the liver, the lymphatic system, the bones, development —all absolutely is the result of vivisection, alone or combined with other means of study.

Apparently it is the contention of the petitioner here that Virchow, Bernard, Darwin, Pasteur and the host of less distinguished servants of humanity who have contributed so much to the well being of mankind by their great discoveries, instead of praise for their beneficial achievements, merit censure for the use of living animals. We cannot adopt such a view. To abolish vivisection would greatly retard the progress of preventive and curative medicine. It would stop the use of animals for the development of all the serums now used to immunize against disease or to relieve and cure after infection. The health and strength of its people are a nation's greatest asset. To adopt the views of antivivisectionists would deprive medicine of one of its most effective agencies of investigation and force a return to empirical and observational methods which, however valuable, fall far short of the demands of humanity. To grant the prayers of the petitioner here would require the government to contribute to the cost of a movement inimical to the safety and health of the people, a result that we think was not contemplated by Congress.

In our opinion vivisection does not come within the legal meaning of cruelty to animals. It is a method of research necessary to human welfare. Such pain or suffering as may result therefrom is not wilfully or wantonly inflicted. We conclude, therefore, that the American Anti-Vivisection Society is not operated exclusively to prevent curelty to animals and so is not entitled to the benefits of section 303 (a) (3) of the Revenue Act of 1924.

Reviewed by the Board.

Decision will be entered for the respondent.

STERNHAGEN and MURDOCK, concurring: When the Board concludes, as it properly and correctly does, that vivisection is not necessarily cruelty to animals within the meaning of the statute, the ground for the decision is complete. It is, in our opinion, unnecessary and probably improper to consider the general wisdom of vivisection, and we therefore refrain from participation in the discussion of that question.

SMITH, dissenting: In my opinion the deduction of the bequest to the Anti-Vivisection Society of America is authorized by the statute. Section 303 (a) (3) of the Revenue Act of 1924 provides for the deduction from the gross estate of "The amount of all bequests . . . to or for the use of any corporation organized and operated exclusively for religious, charitable, scientific, literary, or educational purposes, including the encouragement of art and the prevention of cruelty to children or animals. . . ." The statute is concerned only with the "purpose" for which the corporation was organized and operated. The discussion in the majority opinion as to whether the practice of vivisection is in a legal sense a cruelty to animals or beneficent to mankind goes beyond the necessities of the case. The evidence pertaining to the organization and operation of the American Anti-Vivisection Society seems to me to indicate clearly that its purposes and practices were directed generally toward prevention of cruelty to animals. I think that the bequest is deductible.

Quo Warranto Proceedings to Test Right to Practice

(State ex rel. Biggs v. Higbee (Ala.), 138 So. 819)

Under the laws of Alabama, quo warranto proceedings may be brought in the name of the state against a person practicing any profession requiring a license or certificate or other legal authorization, calling on him to show by what right or warrant he is practicing. If he fails to produce a license, certificate or other authorization, he may be barred from further practice (section 9932, Alabama Code, 1928). Such proceedings were instituted against the respondent, Higbee, to prevent his treating or offering to treat diseases of human beings without first having obtained a certificate of qualification from the state board of medical examiners. Evidence showed that he had treated patients by massage, electricity, heat and a salve, and the state requested the court to charge the jury to find the respondent guilty if it believed the evidence. This the court declined to do, and an exception was noted. Verdict and judgment were given in the respondent's favor. If Higbee had been prosecuted criminally, such a verdict and judgment would have ended the case, for he could not have been tried again for the same offense. In quo warranto proceedings, however, an appeal is possible, and the state appealed to the Supreme Court of Alabama.

The statute requiring examination of persons undertaking to treat diseases of human beings, said the Supreme Court, covers every form of treatment. It is conceded that the respondent is no doctor; that he is not a chiropractor and that he condemns the practice of chiropractic; that he is no surgeon; that he is no osteopath. The statute, however, does not include only the classes named; it reaches out and includes persons who would treat the ills of human beings by any system whatsoever. It includes those who treat diseases by the system known as mechanotherapy, sometimes called the movement cure. The statute is all inclusive where any system or cure is offered to relieve human diseases. Conceding even that the state was not entitled to have the trial court direct a verdict in its favor, nevertheless the verdict of the jury was contrary to the great weight of the evidence, and the trial court, on motion of the state, should have set the verdict aside. The judgment of the trial court was reversed and the cause remanded for a new trial.

Workmen's Compensation Acts: Refusal of Widow to Permit Autopsy No Bar to Compensation.—The Tennessee workmen's compensation act (Public Acts, 1919, chapter 123, section 25) provides that when the cause of death is obscure or disputed, any interested party may require an autopsy at his own expense. This confers on the employer a right to have an autopsy performed, which he may enforce by proper proceedings and order of the court before which a petition for compensation is filed. There is, however, says the Supreme Court of Tennessee, no provision in the statute making a refusal on the part of the widow to permit an autopsy a bar to her recovery of compensation.—*Lenoir Car Works v. Hill (Tenn.), 44 S. W. 321.*

Wills: Lay Testimony as to Testator's Mental Capacity.—The testimony of laymen as to the mental capacity of a testator and their opinions concerning it are admissible in evidence if the witnesses were well acquainted with the testator and had opportunities to observe him and to form an opinion. If the witnesses do not state facts, or if the facts related and the circumstances proved by them do not constitute evidence of mental incapacity, the opinions of such witnesses do not furnish evidence sufficient to justify the submission of the case to the jury. The fact that the testator was an epileptic is not sufficient to establish mental unsoundness, disqualifying him from making a will, in the absence of expert testimony describing its extent and its effect on his mind and showing that the disease deprived him of his mental capacity to execute a will.—*Bodine v. Bodine (Ky.), 44 S. W. (2d) 840.*

Evidence: Use of Medical Books in Cross-Examining Medical Experts.—The authorities, according to the Supreme Court of Oregon, are apparently hopelessly at odds as to how far counsel, in cross-examining an expert, may use the works of authors recognized as standard authorities by the witness and by the profession to which he belongs. The weight of authority is that it is error for counsel to read to his medical witness in his direct examination extracts from a standard medical work, and then to ask him whether what was read corresponds with the witness' own judgment. On cross-examination, however, when a medical expert is shown the works of a recognized authority and states that he is familiar with them and considers them standard authorities, there is no good reason why he should not be asked if he concurs in the opinion of the author. It would create an anomalous situation to permit the witness by his own oath to qualify himself as an expert on the matter on which he testifies and then to refuse to allow opposing counsel to test his qualifications and truthfulness by the use of authorities that the witness himself says he is familiar with and are standard and so recognized by the members of his profession.—*Kern v. Pullen (Ore.), 6 P. (2d) 224.*

COMING MEETINGS

American Academy of Ophthalmology and Otolaryngology, Montreal, Sept. 19-23. Dr. William P. Wherry, 1500 Medical Arts Building, Omaha, Neb., Executive Secretary.

American Association of Obstetricians, Gynecologists and Abdominal Surgeons, French Lick, Indiana, Sept. 12-14. Dr. Magnus A. Tate, 19 West Seventh Street, Cincinnati, Secretary.

American College of Surgeons, St. Louis, October 17-21. Dr. Franklin H. Martin, 40 East Erie Street, Chicago, Director-General.

American Congress of Physical Therapy, New York, Sept. 6-10. Dr. F. B. Balmer, 185 North Wabash Avenue, Chicago, Secretary.

American Hospital Association, Detroit, Sept. 12-16. Dr. Bert W. Caldwell, 18 East Division Street, Chicago, Executive Secretary.

American Physical Therapy Association, Detroit, September 28-30. Dr. C. C. Vinton, 241-02 S. Conduit Blvd., Rosedale, N. Y., Secretary.

American Roentgen Ray Society, Detroit, September 27-30. Dr. Eugene P. Pendergrass, 3400 Spruce Street, Philadelphia, Secretary.

Associated Anesthetists of the United States and Canada, New York, October 17-21. Dr. F. H. McMechan, 318 Hotel Westlake, Rocky River, Ohio, Secretary.

Association of Military Surgeons of the United States, Hartford, Conn., October 20-22. Dr. J. R. Kean, Army Medical Museum, Washington, D. C., Secretary.

Central Association of Obstetricians and Gynecologists, Memphis, Tenn., September 15-17. Dr. E. D. Plass, University Hospital, Iowa City, Secretary.

Colorado State Medical Society, Estes Park, Sept. 8-10. Mr. Harvey T. Sethman, 227 16th Street, Denver, Executive Secretary.

Delaware, Medical Society of, Lewes, September 27-28. Dr. W. O. La Motte, 604 Medical Arts Building, Wilmington, Secretary.

Idaho State Medical Association, Pocatello, Sept. 16-17. Dr. Harold W. Stone, 105 North Eighth Street, Boise, Secretary.

Indiana State Medical Association, Michigan City, September 27-29. Mr. T. A. Hendricks, 23 East Ohio Street, Indianapolis, Executive Secretary.

Kentucky State Medical Association, Louisville, October 3-6. Dr. A. T. McCormack, 532 West Main Street, Louisville, Secretary.

Michigan State Medical Society, Kalamazoo, Sept. 13-15. Dr. F. C. Warnshuis, 148 Monroe Avenue, Grand Rapids, Secretary.

Nevada State Medical Association, Reno, Sept. 23-24. Dr. Horace J. Brown, 120 North Virginia Street, Reno, Secretary.

Oregon State Medical Society, Klamath Falls, Sept. 22-24. Dr. Albert W. Holman, 410 Taylor Street, Portland, Secretary.

Pennsylvania, Medical Society of the State of, Pittsburgh, October 3-6. Dr. Walter F. Donaldson, 500 Penn Avenue, Pittsburgh, Secretary.

Utah State Medical Association, Ogden, Sept. 15-17. Dr. Leland R. Cowan, 305 Medical Arts Building, Salt Lake City, Secretary.

Vermont State Medical Society, Burlington, October 6-7. Dr. William G. Ricker, 31 Main Street, St. Johnsbury, Secretary.

Washington State Medical Association, Tacoma, Sept. 12-14. Dr. Curtis H. Thomson, 1305 Fourth Avenue, Seattle, Secretary.

Wisconsin, State Medical Society of, Milwaukee, Sept. 14-16. Mr. J. G. Crownhart, 119 East Washington Avenue, Madison, Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to The Journal in continental United States and Canada for a period of three days. Issues of periodicals are kept on file for a period of five years only. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending, but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

American Journal of Physiology, Baltimore

Changes in Blood Associated with Fever Induced by Killed Bacillus Coli. M. G. Banus and E. Ginsburg, Boston.—p. 106.

Studies in Physiology of Vitamins: XVIII. Measurements of Vitamin B Requirement in Several Species of Animals. G. R. Cowgill, with Collaboration of H. J. Deuel, Jr., A. H. Smith, B. H. Klotz and H. H. Beard, New Haven, Conn.—p. 115.

Direct Intra-Arterial Blood Pressure Readings in Man. W. Dameshek and J. Loman, Boston.—p. 140.

Mode of Action of Adrenin and Quantitation of Adrenin by Biologic Methods. A. Rosenblueth, Boston.—p. 149.

Glucose Tolerance in Phlorhizinized Dog as Affected by Renal Vessel Ligation and Insulin. L. A. Goldstein, A. J. Tatelbaum, S. Ehre and J. R. Murlin, Rochester, N. Y.—p. 166.

Studies on Possibility of Gluconeogenesis from Fat: I. Response of Phloridzinized Dog to Insulin. Estelle E. Hawley, Rochester, N. Y. —p. 185.

Physiologic Effects of High Frequency Current: II. Further Studies on Respiratory Metabolism of Anesthetized Dogs. E. S. Nasset, Rochester, N. Y.—p. 194.

*Id.: III. Carbon Dioxide and Oxygen Content and Capacity and Concentration of Blood of Anesthetized Dogs. E. S. Nasset, Rochester, N. Y.—p. 203.

Physiologic Effects of High Frequency Current.—Nasset presents experimental data showing that, in hyperthermia produced by high frequency electric current, the blood was concentrated 40 per cent or more. Below a body temperature of 41 C. (105.8 F.) the hemoglobin saturation of the venous blood was increased; above this temperature it was diminished. The loss of water from the blood stream was accompanied, and probably partially compensated for, by a large storage of corpuscles in the spleen. The carbon dioxide content of venous blood was reduced as much as 30 per cent. The alkali reserve, as measured by carbon dioxide capacity, was decreased but to a lesser extent than the carbon dioxide content. It is suggested that this disturbance in the acid base relations of the blood is a consequence of three factors; namely, hyperthermia, hyperventilation and a greatly accelerated metabolic rate.

*Diphtheria Toxoid Precipitated with Alum: Its Preparation and Advantages. D. M. Wells, A. H. Graham and L. C. Havens, Montgomery, Ala.—p. 648.

Effect of Lead Arsenate Spray on Oranges.—Nelson and Mottern present data to show that oranges produced by trees sprayed with lead arsenate differ in chemical composition from normal oranges. The most pronounced difference is a reduction in acidity of the juice; there is also a decrease in sucrose, with a corresponding increase in invert sugar. The arsenic content of the edible portion of the orange was not changed by spraying the tree with heavy doses of lead arsenate. The vitamin C content of oranges from trees sprayed with lead arsenate was found to be considerably lower than that of oranges from unsprayed trees of the same variety and the same degree of maturity. The processing of oranges as practiced by the Plant Quarantine and Control Administration to destroy larvae of the Mediterranean fruit fly did not change the character of the sugars, citric acid or vitamin C content of the fruit.

Public Health Aspects of Frozen Foods.—Fellers calls attention to the fact that fish, meats, poultry, eggs and oysters are especially well preserved by freezing because they retain more nearly their fresh appearance, flavor and character than fruits or vegetables. Most fruits when frozen with sugar retain their flavor well. Vegetables are the most recent addition to the list of frozen foods. Though some varieties freeze well, others do not. Spoilage occurs quickly in vegetables after defrosting. Little change occurs in the chemical, enzymic or nutritive properties as a result of freezing. The changes are largely physical. Freezing greatly reduces the number of micro-organisms present in foods and prevents their multiplication. Emphasis must be placed on the prompt utilization of frozen foods. Until more is known about the subject, frozen products should be consumed while still frozen or within a few hours after defrosting. The ready availability of a large variety of frozen foods at all seasons will serve to give variety and balance to the human diet and should aid in decreasing nutritional deficiency diseases.

Diphtheria Toxoid Precipitated with Alum.—Wells and his associates state that complete precipitation of toxoid with aluminum and potassium sulphate results in a purified product. More than 50 per cent of the original protein remains in the filtrate. A weak toxoid may by this procedure be concentrated to any desired degree. The alum precipitate has a high antigenic value. A single injection of 0.5 cc. in guinea-pigs protects against 50 to 100 minimum lethal doses of toxin injected four weeks later. A single injection of 1 cc. in ninety-eight Schick-positive children resulted in a negative test eight weeks later in ninety-two (94 per cent).

Sex Ratio in Migraine. W. Allan, Charlotte, N. C.—p. 1436.

Diagnosis and Treatment of Tumors of Brain: Review of Symposium at First International Neurological Congress. F. C. Grant, Philadelphia.—p. 1447.

Histologic Diagnosis of Brain Tumors.—Bailey states that the histologic nature of a brain tumor should be known before operation, because the operability of the tumor and the method of attack should depend to a certain extent on the histologic structure of the tumor. This is rarely possible to predict, up to the present time, in the case of tumors of the nerve tissue itself. When the surgeon discloses a tumor at operation, the author still believes that there are cases in which his attack should depend on the histologic nature of the lesion, and he is rarely sure enough of the nature of a glioma from the gross appearance to be willing to base his therapeusis thereon alone. There are two methods of determining during operation the nature of the tumor apart from the gross appearance. One is the method of supravital examination recently reported by Eisenhardt. The author has had several years' experience with this method and has not been able to become sufficiently expert to be willing to base his diagnosis on this method alone. It is possible in this way to distinguish between a meningeal tumor and a glioma, for example; but one encounters plenty of difficulty in distinguishing the different types of gliomas from each other with all of the resources of microscopic technic. The other is the method of frozen sections, and this is still the most reliable, for the differentiation of the types of gliomas demands a knowledge of the architectural arrangement of the cells as well as of the structure of the individual cells. After the operation, either from operative specimens or from the necropsy, one obtains material that is useful for microscopic study. It has no longer much immediate practical value, except, perhaps, in the case of the operative specimen for making a prognosis. The author, for finer histologic study, employs three fixatives, either Zenker's or Bouin's fluid, a diluted formaldehyde solution ("solution of formaldehyde U. S. P." 1, water to make 10) and Cajal's formaldehyde-bromide solution. Others are rarely needed.

Ventriculography and Encephalography.—Grant is convinced that in patients with increased intracranial pressure, suspected of having a tumor of the brain, the air should be introduced by direct bilateral ventricular tap and not by lumbar puncture. Ventriculography gives more accurate information as to the position of a mass lesion with less distress and greater safety to the patient than does encephalography. But in patients without increased tension, for a differential diagnosis between atrophy, sclerosis and tumor, or between traumatic neurosis and true posttraumatic encephalopathy, for prognosis in epilepsy, birth trauma or degenerative disease, or for therapy in posttraumatic headache, an outline of the lateral ventricles and subarachnoid channels should always be obtained by encephalography.

Changes in Brain in Fatal Injury to Head.—Rand and Courville describe the changes in classic neuroglia as the result of injury to the human brain. In the first few days following trauma, the astrocytes in the immediately adjacent area undergo regressive change with the formation of ameboid glia. In the zone nearest the point of injury the cells undergo complete destruction. Beyond this zone of destruction, active proliferation takes place. Here, within a few hours after injury, double nucleated forms indicate active direct cell division. In a rather narrow intervening zone, apolar, bipolar and unipolar forms have been found, which, because of their ready impregnation with gold sublimate, are probably viable cells. This is furthermore suggested by the presence in these cells of double nuclei having normal morphologic characteristics. The authors have interpreted these elements as regressive forms capable of reversible reaction. Gliosis occurs only as a result of tissue destruction. The degenerating tissue probably serves as a chemical stimulant to the regional astrocytes. Extensively damaged brain tissue, which requires a rather prolonged activity on the part of the phagocytic mesoglia, delays for a considerable period the formation of the ultimate glial scar. The astrocytes taking part in this delayed reaction are themselves often victims of regressive change, particularly of a hyaline nature. Judging from studies in comparatively recent cases, it seems likely that the neuroglial reaction is a purely local affair and consequently that generalized gliosis following head injury does not occur. The remote clinical sequelae of such injuries are largely to be interpreted on the basis of focal and distant cortical injuries. In addition, there are numerous interruptions in the connecting pathways incident to focal and subcortical injury, together with the changes following widespread petechial hemorrhages.

Foci of Demyelinization in Diffuse Sclerosis.—Wertham calls attention to the fact that small foci of demyelinization may occur in the spinal cord in diffuse sclerosis far from the large lesion in the cerebrum. These foci are primary and not due to secondary degeneration. In one case reported by the author they were similar to the plaques of multiple sclerosis, and in another case they resembled the lesions in subacute combined degeneration. Small areas of demyelinization in the cortex also, not previously described in this condition, were demonstrated in diffuse sclerosis. These small foci of demyelinization in the spinal cord and in the cortex are of the same type as those found in multiple sclerosis and dementia paralytica. The demonstration of these small lesions in the cortex and the spinal cord in diffuse sclerosis shows that there are forms of diffuse sclerosis that resemble multiple sclerosis so closely that in the absence of etiologic knowledge they cannot be distinguished from it.

Resection of Pylorus.—Thompson reports a comprehensive study of the effects of resection of the pylorus on the secretory and motor functions of the stomach. The manner of approach is different from that of any clinical or experimental investigation reported previously. The method is based on the application of certain standard and specially devised surgical operations to the normal stomachs of dogs. The physiologic effects of the operations are observed by gastric analysis and by roentgenologic examination. Contrary to prevailing opinion, and despite the fact that the pyloric sphincter regulates the emptying of the stomach and the admission of duodenal juices into it, resection of the sphincter, combined with Polya gastrojejunostomy, does not lower the acidity of the gastric contents nor hasten emptying of the stomach. Graduated multiple resections of the pylorus confirmed the prevailing belief that the pylorus is essential to physiologically normal gastric secretory function. A roughly quantitative relation between the amount of pylorus present and the efficiency of secretion is suggested. The fact that widening of the outlet of the stomach does not shorten its emptying time also is contrary to the general conception. The most important contribution resulting from this study refers to the apparent and real secretory functions of the pylorectomized stomach. The use of histamine and the Pavlov pouch disclose that the fundus, after removal of the pylorus, continues to secrete gastric juice having normal acid values. The most important factor in the secretion of gastric juice by the pylorectomized stomach is the cephalic phase of secretion as revealed by the performance of vagotomy. Achlorhydria occurring after pylorectomy is only apparent and is the result of neutralization by the duodenal juices and the food. In the past the importance of the duodenal juices in this respect has been overemphasized, whereas the neutralizing capacity of the food has not been stressed sufficiently.

Duodenal Diverticulum.—According to Harris, duodenal diverticulum is relatively common, being present in approximately 1 per cent of all gastro-intestinal roentgen examinations Three cases are reported in a series of 400 such examinations over a period of three years. Polgar's classification into genuine and pseudo diverticula is advanced as the most logical for the clinician, the roentgenologist and the surgeon, leaving histologically correct classifications to the pathologist. The genuine diverticulum is, etiologically, due to a congenital defect or weakness with superimposed pathologic changes causing increased intra-intestinal pressure. The pseudodiverticulum is primarily due to a preexisting pathologic condition that weakens or breaks through that immediate portion of intestine Practically all diverticula occur in patients past middle age. Diverticula vary considerably in size and number. Constant symptoms are (1) the periodicity of the attacks, (2) the feeling of well being in the morning, with pain and vomiting coming on toward evening, and (3) the relief from symptoms on lying down. It is emphasized that these and other probable symptoms are due to the superimposed diverticulitis. The complications and not the anatomic disturbance cause all symptoms, the diverticulum, alone, being innocent. The roentgen signs alone are diagnostic of diverticulum and also establish the diagnosis of diverticulitis Other things being equal, any slowly emptying diverticulum which is probably complicated by diverticulitis is best treated surgically.

Food Factors Influencing Hemoglobin Regeneration.—According to Rose and Vahlteich, the cure of nutritional anemia induced in rats by milk feeding may be accomplished in six weeks by supplementing milk with whole wheat, prepared bran, or oatmeal in quantities to furnish as much as 0.2 mg. of iron daily. Copper as well as iron plays a part. A hydrochloric acid solution of whole wheat or of bran ash does not give quite as good regeneration as the original food material. The average hemoglobin increase with the ash of 6 Gm. of whole wheat was 7.8 Gm. per hundred cubic centimeters of blood, about the same as with iron and copper supplements to white flour, while that of the original wheat was about 30 per cent higher. The difference between the hemoglobin regeneration induced by the ash of 1.8 Gm. of prepared bran and the corresponding quantity of the bran itself was less striking but in the same direction.

Studies in Physiology of Vitamins.—Burack and Cowgill made a study of the dextrose tolerance of dogs subsisting on a diet lacking undifferentiated vitamin B. The effects of the concomitant fasting were adequately controlled. A definite decrease in dextrose tolerance was exhibited by both the vitamin B-deficient animals and the controls. The degree of the disturbance was directly proportional to the severity of the fasting. In five polyneuritic animals the vitamin was administered in the form of a preparation containing a considerable amount of carbohydrate, so that it was not possible to conclude whether the observed improvement in dextrose tolerance was due specifically to the vitamin. In two experiments a concentrate of the antineuritic factor practically devoid of carbohydrate and suitable for parenteral administration was available. Intravenous injection of this product was made into the dogs exhibiting the characteristic nervous manifestations of vitamin B deficiency. Despite the removal of the symptoms by this concentrate there was no significant effect on the carbohydrate tolerance Ingestion of food, however, was promptly followed by a return of the dextrose tolerance to normal. On the basis of their study the authors conclude that the decrease in carbohydrate tolerance shown by animals deprived of vitamin B is the result of the accompanying inanition The view that vitamin B plays a specific rôle in the metabolism of carbohydrate is not supported by their investigation

Galactose Tolerance of Normal and Diabetic Persons.—Roe and Schwartzman present experimental data which show that galactose is well tolerated by diabetic persons when given in large doses. The administration of galactose in smaller amounts along with other foods should result in even better tolerance and less urinary excretion. It therefore seems probable that galactose might be made a valuable adjunct to the diet in the clinical management of diabetes mellitus. The use of a sugar that has nutritive value and a satisfying sweetness, and whose administration by mouth produces practically no greater saccharemia in diabetic persons than in normal subjects, should mark considerable advance in the control of diabetes mellitus and its undesirable consequences, such as diabetic retinitis and endarteritis, conditions which are presumably etiologically related to hyperglycemia The authors' work demonstrates that galactose ingestion by the diabetic person does not produce the hypersaccharemia characteristic of dextrose ingestion, and that this is apparently because insulin is not necessary for the anabolism of galactose

Menopausal Insanity and Bacterial Toxemia.—Moorhead considers it of importance to examine every case of insanity occurring at the climacteric for possible septic infection. He reports a case of menopausal insanity that was apparently due to focal sepsis. For most of the time the patient was unable to speak, to stand or to walk. All her muscles were excessively flabby; she apparently did not recognize people. There was dribbling of saliva all the time, constant incontinence of urine and feces, and her expression was quite devoid of any intelligence. There was sobbing and crying sometimes nearly all day. She seemed quite hopeless. During ten months, with the exception of a short period of distinct mental improvement, she became from the psychologic point of view progressively worse. There was extreme depression, frequent fits of weeping, sometimes extreme restlessness with shouting. The idea was suggested that a hysterectomy might possibly relieve the symptoms. A complete hysterectomy was performed, both ovaries being removed at the same time. The excised uterus was found to be in a much more septic condition than had been imagined. From the physical point of view the patient stood the operation well, and, apart from a mild heart attack three weeks later, probably caused by small emboli reaching the lungs, she made an uninterrupted recovery. The most striking result of the operation, however, is the fact that almost immediately after the operation her mental condition showed a most remarkable improvement. A week before the operation, an experienced alienist regarded her condition as one of hopeless presenile dementia. Three weeks after the operation, she was able to reply sensibly to simple questions. After a week she began to notice her surroundings and to recognize her friends and relatives. In a fortnight there was evidence of returning memory. From that day there has been progressive improvement physically and mentally. Five months after the operation, the patient was able to go out for daily walks and drives; she eats well, sleeps well, and enjoys the visits and conversation of her friends. She writes short letters, can read the newspaper for a short period, and her face has recovered its old expression of intelligence.

Menopause and Its Complications.—FitzGibbon enumerates the causes of pathologic states of the uterus at the time of the menopause as follows: (1) ascending infection promoted by stagnation of menstrual or other discharges from the uterus and cervix; (2) laceration and damage during childbirth of the cervix and parametric tissues, exposing those tissues to chronic infection; (3) septic infection following childbirth; (4) gonococcal infection on which secondary infection has supervened—far less common than the preceding, and (5) growth and influence of neoplasms, chiefly uterine fibroids. The pathologic lesions that are produced and influence the course of the menopause are: (1) chronic hyperplasia of the body of the uterus; (2) chronic metritis with chronic cervicitis, and (3) chronic cervicitis, with or without parametric induration. Associated with these conditions there is an increased vascularity; the smaller arteries are hypertrophied, and there is venous congestion. During the active child bearing period of life these lesions produce varying degrees of leukorrhea calling for palliative treatment, such as routine douching, applications of caustics, and curettages. These treatments have no more curative effect on the chronic infection than gargles in chronic tonsillitis. Amputations of the cervix effect cures when the portio vaginalis is the part involved, but they frequently stop far short of removing the main center of infection, which is the supravaginal portion. When the period of the menopause is reached, and atrophy of tissue has proceeded, the vitality of the tissues is reduced, and the production of toxins from the chronic infection is increased. The local condition, leukorrhea, has been accepted as inevitable, while increased menstrual loss reduces the woman's resistance but is considered a necessary part of the menopause. The author in no sense advocates hysterectomy as a universal treatment for ill health at the time of the menopause. The differential diagnosis of the lesions described is a difficult and minute matter. It is seldom possible to make an early decision. In the majority of instances a decision will be reached only after a period of observation, but the lesions which exist at the onset of the menopause can be observed and should be sufficient to indicate treatment by hysterectomy if the ill health increases. Serious and permanent damage may thus be prevented. When hysterectomy is resorted to, it must be of the total type. The failure to observe the benefits of hysterectomy in these cases has in the past resulted from the common practice of performing the high partial operation: this relieved the menstrual symptoms but did not remove the toxic element.

Phototherapy in Erysipelas.—Davidson presents a report on fifty-one cases of erysipelas treated by exposure to an artificial source of ultraviolet radiation, the exposure being from one and a half times to twice that required to produce a definite erythema on normal skin. The treatment of erysipelas, particularly the early case, by ultraviolet radiation appeared to give better results than other methods in use. The method is easily applied, usually available, devoid of danger, clean and inexpensive. The technic is simple and can be carried out with any ultraviolet lamp of known efficiency. Before treatment is begun, any soothing preparation previously applied to the part, especially if greasy, is carefully removed from the affected area and surrounding skin. All patients, except infants, are exposed for five minutes with the arc at a fixed distance of 12 inches (30 cm.). In the case of infants a slightly shorter exposure is employed, when the actual individual erythema dose is not estimated. In all cases part or all of the inflamed area, according to its extent, is included in the exposure, with a margin of about 1½ inches (3.8 cm.) of healthy skin when this is possible, the rest being protected by some light covering. In facial and head cases generally, the eyeballs are protected by small pads of absorbent cotton fixed by a narrow strip of adhesive plaster, but the eyebrows are left uncovered, and each part of the spreading edge is systematically exposed to rays falling, as far as possible, perpendicularly. When the entire involved area is easily covered by one exposure this completes the treatment, but occasionally part of the lesion, which at the time of admission is assumed to have subsided, is neglected and has to be treated later. In the few cases in which definite extension occurs through the erythematous area, the treatment is repeated one or two days later if a margin of healthy skin can still be included. Following the irradiation, the affected part is left uncovered, or at least without dressings, except when pain is a prominent feature, and in these lint wrung out in cold water and frequently renewed is sufficient. All other treatment is symptomatic.

Bright's Disease.—According to Gainsborough, toxic nephritis is a disease in which progressive changes in the kidneys, of the most variable severity, are associated with a clinical picture which presents a unity, despite the differences which are due mainly to the length of duration of the process. From the most acute forms to the mildest forms, every degree of severity can be found, and it is impossible to find natural subdivisions. "Nephrosis" comprises a clinical and metabolic syndrome which is superimposed on all cases of toxic nephritis to a degree depending mainly on the mildness of the nephritis and consequently on the length of time available for this syndrome to develop. The most nephrotic cases are those in which the nephritis presents the mildest histologic changes and the slowest rate of progression. All cases of toxic nephritis present a progressive loss of renal function and tend to terminate in uremia. In the most nephrotic cases this change is so slow that in such cases the patients die usually from intercurrent infection or recover before loss of renal function, as usually measured, is recognizable. The nature of this progressive loss of renal function is identical in all cases of toxic nephritis, whatever the cause and whatever the severity.

Spontaneous Subarachnoid Hemorrhage.—Hall believes that in any individual case of spontaneous subarachnoid hemorrhage the question of death or recovery depends largely on whether the bleeding point is capable of firm closure or not, and this in turn depends on its size and surroundings. These cannot be known during life. Provided the patient is kept at rest, and lumbar puncture is done at the onset for diagnostic purposes, and incidentally to a sufficient extent to relieve any increased pressure at the time, it is unnecessary to expose the patient to the discomfort of repeated punctures, unless the pressure symptoms persist or get markedly worse. Slight exacerbations may occur from time to time but are probably not due to further bleeding, and they disappear when left alone.

Cardiac Irregularities During Chloroform Anesthesia.—Hill states that disturbances of cardiac action which generally elude clinical observation can be detected electrocardiographically during chloroform anesthesia. They occur in about 50 per cent of cases and are of the nature of multiple ventricular extrasystoles. These on occasion may be very numerous, and the condition then resembles the "multiple ventricular tachycardia" so characteristically found in the cat, and well known as a precursor of fatal ventricular fibrillation. The author believes that the danger of choloroform for induction probably lies in its tendency to produce these disturbances.

Rapid Roentgenographic Exploration of Appendix. S. Kadrnka and R. Sarasin.—p. 990.

Rapid Cholecystography.—By giving an injection of dextrose before the injection of tetiothalein sodium, Antonucci obtains cholecystograms in a shorter time than is possible by the method now in use. The essential part of his method consists in an intravenous injection of 125 cc. of a 40 per cent solution of dextrose followed after a ten minute interval by an intravenous injection of from 2 to 3 Gm. of tetiothalein sodium in the usual solution. When possible, it is well to prepare the patient by placing him on a low carbohydrate diet for three or four days previous to the test to aid in the complete absorption of the sugar mixture by the liver, but this is not necessary. When the patient is prepared only by fasting during the night and morning hours prior to the test, the intravenous injection of the sugar and tetiothalein sodium may be followed by 25 units of insulin given subcutaneously, but this is also not necessary. By this method visualization in normal individuals begins from one-half to one hour after the injection and reaches a maximum two hours after injection. The author thinks that the explanation for the rapidity of visualization by this method lies in the fact that dextrose is necessary for the absorption of tetiothalein sodium by the liver. This explanation was supported by a study of the sugar curves following injection of tetiothalein sodium alone and also by the results of injection of this substance alone into diabetic persons. It was demonstrated experimentally that the author's method produces an afflux of bile after half an hour, two or three times that produced in Graham's method; this rapid and abundant afflux of bile charged with iodine helps to account for the rapid visualization. Strawberry gallbladders were filled not at all or slowly. Whatever the explanation, failure of the gallbladder to become filled by this method is, in the absence of other abdominal disturbances which might account for it, a certain sign that the organ is diseased.

Auxoneurotropic Action of Epinephrine and of Solution of Pituitary.—In animal experiments for production of anesthesia by artificial perfusion of the brain, Friedemann and Elkeles found that intravenous injection of epinephrine and of solution of pituitary reduced the threshold value of anesthetics such as ethyl urethane, paraldehyde and alcohol to about one fifth; that is, one fifth of the usual anesthetic dose was sufficient to produce anesthesia. Other hormones, such as insulin and thyroxine, did not have this effect. It was also noted that the toxic action of strychnine and of cobra toxin was increased fivefold by epinephrine and solution of pituitary. By special methods of staining it could be demonstrated that the auxoneurotropic action of epinephrine and solution of pituitary can be traced to an increased invasion of neurotropic substances into the brain. Substances that are not neurotropic, such as arsphenamine, antitoxin and trypan blue, do not enter the brain even under the influence of epinephrine or solution of pituitary. The authors discuss the significance of these observations for pharmacologic, chemotherapeutic, serotherapeutic and pathogenic problems.

Canned Vegetables and Fruits in Feeding of Children.—In order to determine whether canned fruits and vegetables are suitable for feeding nurslings and children, Reiche made observation on 613 inmates of a children's home, who for shorter or longer periods were fed with canned vegetables. The children were subjected to regular examinations, the urine was tested, the first signs of rickets were watched for, and occasionally roentgen tests were made. These observations revealed that factory canned fruits and vegetables can be used for long periods in the diets of nurslings and children without causing disorders that are produced by vitamin deficiency.

Operation of Double Harelip.—Hagentorn declares the following rules as essential for a successful operation of harelip: (1) complete preservation of all the tissues, because the misformed lip has no excess of tissues; (2) utilization of each special tissue for the purpose for which it was intended by nature. He considers operations that do not follow these rules no longer justified. For the double harelip he recommends two operations. He describes his operative technic. The first intervention has the purpose to repair the cleft, preserve the philtrum and form the red portion of the lip. The second operation can be performed from three to four weeks after the first one, or later. It is done to raise and narrow the broad, flat nose, to improve the septum and philtrum, and to bring the lip downward and forward. If it is considered how much the correction of the malformation means to the patient, and that the second intervention can be made at any time later (because the first operation overcomes the main deformity), the greater complexity of the two-stage procedure cannot be considered as a contraindication, for the better results justify it.

Results of Herniotomy in Femoral Hernia.—The review of a large material convinced Husted that operations for femoral hernia have a larger percentage of relapses than is usually admitted, but it also showed that a special type of operations, namely, the so-called inguinal methods, give better results than any others. In these interventions the inguinal canal is opened and the hernial sac extirpated high. Then the femoral and inguinal canals are closed by suturing the musculature and Poupart's ligament to the pelvic rim (pecten ossis pubis).

Biologic Behavior of Uterine Muscle of White Mice. F. Kammerhuber. —p. 1531.
Anencephalus in Twin Pregnancy. S. Simon.—p. 1536.

Time of Conception.—Bolaffio disagrees with Knaus and Ogino (abstr. The Journal, Oct. 12, 1929, p. 1183, and June 18, 1932, p. 2257), who assume that there is a period of physiologic sterility during the menstrual cycle. He believes that there is no period of absolute sterility but that there are considerable fluctuations in the degree of conception capacity. Conception is most likely during the first twelve days of the menstrual period, the seventh and eighth days being the most fertile. During menstruation the first two days are less fertile than the following. The conception capacity decreases from the ninth day on. Least fertile is the period between the seventeenth and the twenty-eighth day, but to consider conception an impossibility during this period is not warranted. If the menstrual period is longer than twenty-eight days, the time immediately preceding menstruation has a considerable degree of fertility. The author also expresses the opinion that the conception of boys is most frequent during the period of greatest fertility, and he thinks it probable that the degree of maturity of the ovum is responsible for this. He also discusses causes and time of the rupture of the follicle.

Disturbances of Sympathetic Nervous System: Organoneurosis, Organopathy and Cerebropathy. E. M. Kastanayan.—p. 342.

Venous Pressure.—Vilkoviskiy and Umanskiy used Valdman's apparatus in the determination of venous pressure. Sodium citrate, instead of water, in the manometer minimized the possibility of blood clots. It has been suggested that decompensation is related to stagnation in the greater circulation and consequently to venous pressure. Plesch's method, which the authors used for determination of the venous pressure, is based on the fact that pressure in the region of the liver during decompensation causes a stagnation in the right ventricle and the central veins and then a dilatation in the jugular veins. The phlebogram registered such changes. The authors examined thirty-nine patients with compensated and forty-four patients with decompensated cardiac conditions and conclude that absolute figures of venous pressure are not of clinical interest. In normal and compensated cardiac conditions Plesch's test registers an increase of venous pressure of from 2 to 10 mm. of water, whereas in patients with decompensation the venous pressure is always increased in excess of 10 mm. of water. Plesch's test may be used in the early diagnosis of decompensation as well as for a control method in treatment.

Diets in Treatment of Ulcer of Stomach.—Kushelevskiy states that during the last eight years he has observed 300 patients with gastric and duodenal ulcers and has treated 155 of those with the more severe and complicated ulcers with a modification of Yarotskiy's diet. The entire treatment was divided into three parts: The first part, which lasted from eight to ten days, consisted of a strict butter and egg-white diet, not exclusive of liquids; the diet during the second and transition period (from four to six days after disappearance of pains) included thick porridge, no salt, and with 100 Gm. of butter for luncheon and dinner and two soft boiled eggs for breakfast, and in case of continued pains, a glass of egg-white for an interval of from three to five days; at the beginning or end of the third week, the third part of the diet included besides the thick gruel also tea with milk, fried eggs, white biscuits, milk soups, purée, compotes, and small quantities of milk (preferably citrated). To combat hypersecretion the author administered extract of belladonna (from 0.015 to 0.02 Gm. three times a day) as well as alkalis and magnesium carbonate. The first period relieved the pain and gave the stomach more modulated motor function, the second served as a test for treatment and the third period brought the patient back to a normal diet and built up his strength again. The results were favorable in 95 per cent of the patients treated. The author believes that Yarotskiy's diet did not decrease gastric secretion—whenever that occurred, it was probably due to psychic inhibition. In 50 per cent of the patients the gastric secretion was increased, in 23 per cent it was decreased, and in 27 per cent it was unchanged. Roentgenograms before and after the diet did not demonstrate a parallelism between motor and secretory function. The alleviating action of the diet is not due to a lowered acidity but to elemination of the pyloric spasm and irregularities in motor function. The strict albumin-fat diet with sparing of carbohydrates during the first period results in acidosis, ketosis and acetonuria, which disappear when the diet is expanded; while the large quantities of butter may have a therapeutic effect through the resultant cholesteremia.

Case of Poisoning with Etheroleum Sabinae with Unusual Picture. E. Wessén.—p. 417.
*Histamine in Diagnosis of Latent Jaundice. H. af Ekenstam.—p. 426.
*Sedimentation Reaction in Fractures. T. Olovson.—p. 433.

Histamine in Diagnosis of Latent Jaundice.—Af Ekenstam concludes that the histamine test cannot replace the usual methods for determination of the bilirubin content of the blood serum, but because of its simplicity it can be a useful guide to the practitioner.

Sedimentation Reaction in Fractures.—Olovson says that in all of 121 cases of uncomplicated fractures and four of hemarthrosis there was a rise in the sedimentation speed of the red blood corpuscles above the normal value, the rise appearing during the first twenty-four hours in 75 per cent of the cases. The maximum was reached from the fifth to the seventh day and was followed by a slow decline, with return to normal value after well advanced consolidation. This reaction depends partly on the extent of the lesions of the bones and soft parts, partly on the patient's age. How significant the reaction may be from the practical clinical point of view, as an indication of the consolidation and healing of the fracture, cannot now be determined.

PRACTICAL REFLECTION ON CERTAIN GASTRO-ENTEROLOGIC PROBLEMS AND TRENDS

CHAIRMAN'S ADDRESS

GEORGE B. EUSTERMAN, M.D.
ROCHESTER, MINN.

Those whose major interest and energy are taken up with the gastro-enterologic field of medicine realize that a great many morbid functional and organic states to which human flesh is heir find expression in disorders of the digestive tract. By virtue of this fact, he who would most successfully cope with the problems that arise daily should be, essentially, a versatile clinician whose point of view is broad. As the subject matter is obviously too huge to warrant general consideration, I shall confine my observations to two entities which an eminent American professor of medicine, in a practical though obviously light mood, said constituted the only diseases of the stomach, namely, ulcer and carcinoma.

Exact knowledge concerning the etiology and pathogenesis of any disease is of paramount importance in its prevention, cure or complete eradication. Yet, in spite of unprecedented scientific progress in the last half century, one is witness to the paradox of knowing little or nothing about the causation and mode of development of many common organic diseases. Knowledge of cause and development is mainly confined to morbid states, the result of specific bacterial infection, or of bacterial and chemical toxins, to protozoal, fungous or helminthic infestation, states of vitamin deficiency and certain allergic conditions. One need but recall the humiliation consequent on, or the ineffectiveness of, treating along conventional lines a gastric lesion, profound anemia, ophthalmia, diarrhea or jaundice, which on further investigation was proved to be, respectively, due to [illegible] latum, vitamin A deficiency, gastrocolic fistula and carrots! With timely recognition of the causative agent under such circumstances, the therapeutic procedure is obvious and the favorable results are strikingly prompt.

If for no other reason than that peptic ulcer is a highly prevalent disease, directly affecting the health and efficiency of many adult members of every community, one's concern or curiosity should naturally be aroused as to the circumstances which might give rise to this condition. That this subject has been of real interest to members of the medical profession is attested to by an enormous scientific material of international scope, which has recently been summarized and appraised in a comprehensive monograph (of 387 pages) by von Redwitz and Fuss. Hauser's classic contribution to the subject in Henke and Lubarsch's "Handbuch der speziellen pathologischen Anatomie und Histologie," published six years ago, has exerted powerful influence throughout the scientific world. In addition to this may be added the results of numerous and important researches of many investigators, made in the last decade.

Hauser, after calling attention to those varied and familiar factors, any one of which he maintained, can lead to hemorrhagic infarction, erosion and acute ulcers of varying depth, size and shape, summarized his observations as to what makes for chronicity of the lesion in the following manner: It is dependent on the interaction of various factors which already partly constitute the first cause of the acute ulcer, and which are found partly in the anatomic structure of the gastric wall and in the functioning of the stomach, partly first produced through formation of the ulcer itself. In ulcers founded on disease of the vascular element, or on a neurogenic basis, the continued action of either original cause of the ulcer may suffice to render healing more difficult. Accessory to this are the heightened chemical and mechanical (retention, spasm of the vessels and musculature) influences exercising a deleterious effect on the lesion, the very presence of which make such effect possible. Hauser added that all these factors are increased if the patient who has ulcer simultaneously manifests a neuropathic tendency. Hauser's influence is plainly seen in the conclusions drawn by von Redwitz and Fuss.

It seems to be difficult to reconcile clinical facts with conclusions reached in the past. Every one shares a common environment, is subject to the same deleterious influences, and yet the majority escapes the disease. What is it that initiates the process and what are the factors that destine the initial lesion, whatever it may be, to become chronic or complicated? In searching for the possible answer one must at least briefly consider and evaluate certain hypotheses and certain clinical, experimental and pathologic facts.

The modern pathologist apparently remains faithful to the old conception of Virchow that circulatory disturbances in the veins and arterioles of the submucosa are followed by regional necrosis of the mucous membrane, digestion of the devitalized area by the gastric juice, and ulceration. The research worker disputes this conception of the formation of ulcer, because he argues that considerable injury to, or ligation of, the blood vessels in the experimental animal does not result in chronic peptic ulcers. On the other

Read before the Section on Gastro-Enterology and Proctology, at the Eighty-Third Annual Session of the American Medical Association, New Orleans, May 12, 1932.

hand, his researches cause him to maintain that ulcers develop from the mucosa outwardly toward the serosa, largely as the result of chemical and mechanical factors, disharmony between the acid-forming and acid-regulating or neutralizing mechanism. The belief in the causative part played by bacteria, as championed by Rosenow, has many supporters. Konjetzny, Puhl and others champion the theory of inflammation, claiming that gastritis is the etiologic agent. This theory has provoked much discussion and disagreement. Bauer, Draper and others have stressed the importance of the constitutional factor, and as corollaries of these one has the concept of vasoneurotic diathesis of Müller and Heimberger, and that of hyperasthenic gastric diathesis of Hurst and Stewart. Last, but not least, the hypothesis concerned with neurogenic factors, with which the name of von Bergmann is most closely identified, has many proponents at present.

Leaving out of consideration uremic, tuberculous and syphilitic ulcers, various causes have been generally recognized which might give rise to peptic ulcer, such as extensive burns of the skin, embolic and thrombotic processes arising from cardiovascular and venous disease and sepsis, chronic lead poisoning, arteriosclerotic disease of the gastric vessels, disease of the central nervous system, and possibly external trauma, malnutrition or states of vitamin deficiency. Obviously, the majority of patients have no such etiologic background.

An adequate hypothesis concerning the cause of ulcer would have to take into consideration many clinical facts, among which the following, in my opinion, should be emphasized: fairly reliable evidence of a distinct rise in the incidence of duodenal ulcer in the last quarter of a century, an observation confirmed by the investigations of Robertson and Hargis, and others; in its duodenal situation the chronic ulcer makes its appearance in the second or third decade of life; in its gastric situation, in the third or fourth decade, and in America at least it is ten times more common in the former situation than in the latter, and in its primary form, affects men from three to four times, and in its recurrent postoperative form, nine times as frequently as it does women; it is a disease confined almost exclusively to civilized people; it may affect several members of the same family or successive generations; a small group of persons may have an ulcer diathesis, that is, a remarkable tendency to uncontrollable recurrent lesions; in some countries, notably Germany, the preponderance of duodenal over gastric ulcer is much less than in this country, and the incidence according to sex may be equal. To all of this must be added the significance of the provocative effect of physical and nervous fatigue, anxiety and emotional states, seasonal variations and gross indiscretions in eating, smoking and drinking.

As regards the etiologic part played by focal infection, much can be said for and against it. It is quite likely that foci frequently can act as the exciting agent, and on occasion can be the sole cause of the chronic lesion, in view of the fact that there is operative a pathogen of low grade virulence delivered to the circulation in a continuous or intermittent fashion over a long period, during which time the resistance of the host may vary greatly. But critics of the hypothesis of infection call attention to the fact that this mode of origin would not throw light on the incidence of the disease, according to age and sex, in this country, or on the great preponderance of duodenal lesions in both sexes; nor would it explain the recurrence of ulcer among patients from whom all tangible foci had been removed. It has also been my repeated experience that a lesion may heal spontaneously, or as the result of either indifferent or intensive treatment may heal peripherally in the presence of extensive foci. Hemorrhagic erosions or acute ulcers reproduced in the rabbit by inoculation of organisms cultured from foci of human beings apparently never develop into the typical chronic lesions. In my opinion, in view of these facts, the hypothesis that infection is the sole cause of the chronic lesion cannot be unreservedly accepted. That certain micro-organisms may prove the exciting agent, and that it is the better part of evidence to remove all obvious foci in the ulcer-bearing patient, cannot so readily be denied.

The results of experimentation on animals may or may not have been fruitful from the standpoint of clearing up the problem of etiology, even though experimental procedures have been brilliant in inception and successful in execution. It is reasonable to presume that the factors giving rise to a chronic visceral lesion in the human subject cannot be approximated in the acute experiment. But the researches of such representative investigators as Mann, Ivy, Dragstedt and their associates, and, more recently, those of Harper, have thrown much light on problems connected with localization of ulcers, the increase in susceptibility of the mucous membrane to ulcerative processes from the pylorus downward, the traumatizing effect of coarse particles of food, the mode of healing and factors that promote or prevent it, and the comparative part played by mechanical and chemical factors and by mucosal susceptibility in the production of a jejunal lesion.

In recent years, many observers have concluded that the neurogenic factor has not been sufficiently stressed. Even a pathologic anatomist, such as Hauser, ascribes to neurogenic influences the most likely origin of ulcers of young adults, and to arteriosclerosis the majority of lesions appearing among patients in the later decades. In this connection, one must also bear in mind the contributing factor already cited, of the chemical influence of the gastric juice, for free acidity is maximal among men in early adult life. It is also appropriate to recall at this time the high incidence of ulcer among patients with brain tumor and exophthalmic goiter, diseases associated with great irritability of the central nervous system, and among persons living under great nervous strain. Sir Thomas Horder regarded the increase in peptic ulcers and certain other conditions as a product of microbic subinfections of the streptococcus variety. He expressed the belief that this is made possible by the stress and strain of a complex civilization, which tends to lower tissue resistance. The pertinent question was raised as to whether the central nervous system might not have some more definite and direct bearing on infection, or rather on immunity, than had hitherto been thought likely. Horder thought it difficult for any physician to avoid the conclusion that the hustle of modern life, the pace at which people go, the nervous strain involved and the expense of spirit entailed have become a large factor in the incidence of disease, and of diseases of a different type from many with which one was formerly acquainted. Alvarez summarized the effects of these nervous influences as follows: Psychic stimuli of a certain type increase the acidity and peptic activity of the digestive juice, and it is possible that smaller amounts of mucus and the other protective fluids of the stomach may be secreted;

ischemia of the tissues may be produced by spasm, either of the blood vessels or of the muscularis mucosae, or of the main muscular wall of the stomach and bowel: emotion can produce pylorospasm, with stagnation of gastric content and resultant increase in acidity.

The attempts in some quarters to belittle the part played by gastric acidity in the symptoms, pathogenesis and treatment of gastroduodenal ulcer seem unwise. The facts that the lesion is confined to tissues bathed by gastric content, that the uncomplicated lesion becomes symptomless and tends to heal more rapidly with adequate neutralization of the free hydrochloric acid, that recurrent lesions are invariably associated with a high concentration of acid and high peptic activity, that experimental research amply confirms the importance of the chemical factor in pathogenesis, are a few among numerous other salient features to discredit such attempts, in my judgment. It is true that some unhealed benign lesions are associated with hypochlorhydria, or even achlorhydria, especially on the basis of former faulty standards of what constituted normal gastric acidity according to age and sex, and on the basis of a single, occasionally repeated, gastric analysis. Even according to the old standards and in the absence of tests of response to histamine, the majority of such ulcer-bearing patients would reveal an adequate acidity when the gastric content was withdrawn at the height of activity of the lesion.

The significance of nervous and mental influences on the motor and secretory functions of the stomach of man has been commented on by Ivy, a fact which he admits makes highly improbable the elucidation of certain problems in connection with ulcer through animal experimentation. Bollman is also impressed with the significance of natural factors that are capable of altering the activity of the stomach, for example, psychic influences, which appear to be much more powerful than many extensive surgical procedures.

On the other hand, the individual capacity to escape the lesion under conditions highly favorable to its formation is worthy of comment. An increasingly large number of patients who exhibited symptoms fairly characteristic of peptic ulcer, coupled with a psychophysiologic make-up similar to that of the ulcer-bearing patient, failed to reveal fluoroscopic or surgical evidence of the lesion, despite the long-standing nature of the complaint. Among patients with ulcer, as well as among those with pseudo-ulcer, surcease from physical, nervous or emotional stress alleviates or dispels the symptoms. Another group of patients may present symptoms or evidence of acute ulceration, pyloric hypertrophy, hemorrhagic erosion, duodenitis, areal gastritis or gastrojejunitis following gastro-enterostomy, but the familiar, calloused ulcer does not develop. In such cases there is apparently increased mucosal resistance; the factor, or factors, contributing to this have not yet been definitely determined.

In summarizing these observations bearing on the etiology, pathogenesis and symptoms, one cannot easily escape the conviction that nervous imbalance, resulting in disturbed parasympathetic and sympathetic interaction on gastric or duodenal motility and secretion, plays an important, if not an exclusive part, in the symptoms at least, and in the genesis of ulcer itself. When an actual lesion does develop under such circumstances, it seems justifiable to predicate a mucosal susceptibility based on inheritance, or acquired through the influence of infection or other sustained irritant resulting in vulnerability of the gastric and duodenal tissue to the heightened corrosive and digestive action of the gastric juice.

GASTRIC CARCINOMA AND GASTRITIS

A dormant interest in the genesis of gastric carcinoma was reawakened by Hurst in an article published in the *Lancet* three years ago, in which he concluded from his observations that 75 per cent of gastric carcinomas have their origin in preexisting chronic, atrophic gastritis. He stated that achlorhydria was present prior to the disease, and was the result of gastritis. Of further interest was the statement that neither he nor a number of fellow practitioners whom he had consulted had ever seen a case of carcinoma in which free hydrochloric acid was present in the early stage and disappeared as the disease advanced; moreover, he had not been able to discover a single record of such a case. In support of these observations on the high frequency of gastritis associated with benign, and possibly with carcinomatous, lesions, in Germany, he quoted in particular the well known researches of Konjetzny, of Kiel. Hurst designated the first group as gastritis-cancer; a second group, comprising 20 per cent, as ulcer-cancer, which represents those cases due to carcinomatous transformation of a simple ulcer and in which free hydrochloric acid is present throughout.

Much as I should like to, I cannot agree with Hurst in his observations concerning the first group, for the reason that chronic atrophic gastritis coexists with carcinoma only rarely in material available to me. Finally, answer to his interesting observations concerning the secretory status of the stomach prior to the advent of the disease and concerning the influence of the disease on such status will be made in the near future on the basis of clinical and experimental evidence. The observations of Konjetzny and others with respect to the increased incidence of gastritis in its various forms in Germany, especially in association with gastric and duodenal ulcer, are beyond dispute and to a certain degree are justification for the more extensive operative procedures advocated by representative German surgeons. Such gastritis under the same circumstances in this country is conspicuous by its absence in the majority of instances. Konjetzny's conclusions concerning the etiologic relationship of the various forms of gastritis to ulcer and carcinoma have been vigorously disputed by eminent pathologists and surgeons. To explain the great difference in the incidence of gastritis in America and in Schleswig-Holstein, for example, can be best done, in my opinion, by comparison of the habits of eating of the citizens of the two regions. The German custom of partaking freely of more generous amounts of stimulating, although usually mild, alcoholic beverages, as well as of irritating food, seems to be the most likely explanation for the condition, and this opinion is shared by numerous German observers.

ROENTGENOLOGY

Prior to the advent of roentgenologic examination of the alimentary tract as an accessory diagnostic procedure, recognition of organic lesions of the stomach, duodenum and colon depended largely on data derived from painstakingly assembled case histories, careful general examination and analysis of gastric content. It was often necessary to resort to observation in a hospital or to exploratory operation in order to clarify the problem. Determination as to whether an ulcer was gastric or duodenal in situation was possible only occasionally, even though such determination was more or less of academic interest. The clinical training of that period has always stood one in good stead, and fortunate is he who has experienced it.

But with the advent of visual methods of diagnosis, it was soon realized that many ulcers and gastric carcinomas, chiefly those without obstruction or palpable mass, had been previously overlooked, especially in the earlier stages of the disease. Kirklin has called attention to the fact that the golden era of roentgenologic development and achievement occurred during the decade from 1910 to 1920. Since that time its advance has been slow and devoid of striking features, and there has been no outstanding innovation, unless progress in the knowledge of how to visualize in relief the interior of the alimentary tube, as exemplified by the work of Forsell, Fischer, Åkerlung, Berg, Weber and others, may be so considered. Those roentgenologists who are fortunate enough to have adequate material at their disposal, and whose diagnoses are checked, as a routine procedure, in the operating room, acquire skill that usually renders their opinion a veritable "necropsy in vivo." Only by such procedure is it possible, with any assurance, to recognize, among other things, benign tumors, congenital anomalies, small diaphragmatic hernias, phytobezoars, carcinomas of small size, concurrent lesions of the stomach and duodenum and some of their complicating factors, pulmonary and osseous metastasis, and to a large degree the inoperability or operability of a malignant lesion by virtue of its position and extent. The effect of failure or success of nonsurgical therapeutic procedure may be more or less accurately gaged by successive roentgenoscopic examination. The necessity of employing a gastroscope or gastrophore will be in inverse ratio to the skill of the roentgenoscopist. However, lesions such as duodenitis, areal gastritis, gastrojejunitis, a small percentage of noncraterous lesions of the anterior and posterior wall, lesions high on the posterior wall of the stomach and lesions of the small bowel at the anastomosis and beyond may occasionally escape detection. It will be seen that conditions are continually arising which make necessary the closest cooperation between roentgenologist and clinician concerning matters not only diagnostic, but therapeutic and prognostic. With the advent of cholecystography, an invaluable procedure, and of recent technical refinements in roentgenologic diagnosis of colonic lesions, a high degree of diagnostic accuracy has been obtained. Only the pancreas, in many respects, still successfully defies us.

Coincident with the impasse reached by the roentgenologist, there has been a fruitful renewal of scientific interest in gastric physiology, especially with reference to secretory and motor function in health and disease; this eventually will result in clearing away many misconceptions, and will lead to greater diagnostic accuracy. Among many other equally important researches, I am at present mindful of the contributions of Gompertz and Vorhaus, Gorham, Bloomfield and his associates, Castle, Rehfuss, McCann, Bockus, Vanzant and Northrup. As a result of these researches, one is more plainly aware of the diagnostic shortcomings of the ordinary test meal, in the absence of retention, blood and abnormal microscopic elements. There is more authentic knowledge concerning such important features as: (1) the volume of gastric secretion, acidity of the gastric juice and gastric motility simultaneously determined by a reliable method under normal and disease conditions; (2) incidence and significance and eventual prognosis in cases of true achlorhydria; (3) the normal range of free acidity in healthy subjects according to decade and sex; (4) more reliable methods for the determination of peptic activity, and (5) a realization of the presence and significance of other constituents of the gastric juice essential to the maintenance of health and life itself.

TREATMENT

In the treatment of a disease such as chronic gastric and duodenal ulcer, in which knowledge of fundamentals is still more or less incomplete, or concerning which there is no universal agreement, a variety of both medical and surgical therapeutic measures naturally exists, and new ones keep springing up as they always have in the past. In the last decade the rise and fall of the much vaunted protein therapy, and, more recently, the inception of the mucin regimen of Fogelson and the pepsin treatment of Glässner, have been witnessed. Although these various procedures have their virtues, which cannot be appraised by immediate results, and should be encouraged, it is not improbable that methods of the present day may eventually appear crude indeed in the light of future progress. Nevertheless, as the result of a summation of experiences, there is general agreement that the dietotherapeutic principles, aside from proper nutritive and digestive qualities, should embody freedom from chemical, mechanical and thermal irritation; that every ulcer-bearing patient should first have the advantage of medical treatment, especially young subjects whose disease is in the early, uncomplicated stage; that not only the local lesion, but the patient as a whole, receive serious consideration; that the treatment be thorough and sustained and that the patient's complete cooperation be secured if possible. It is a common observation that a period of complete mental and physical rest, and proper dietetic measures, alone may suffice to achieve a satisfactory result, if the capacity for healing is inherently great.

In recent years one has seen a growing tendency for closer cooperation between the surgeon and the internist, especially in the larger private and public medical institutions, with respect to supervision of ulcer-bearing patients. Such pooling of diagnostic and therapeutic resources has not only redounded to the mutual scientific edification of surgeon and internist, but to the welfare of the patient, which is all-important. It has made possible more discriminating selection of patients for either medical or surgical treatment, more careful preoperative preparation wherever indicated and more intelligent postoperative care. It has stimulated fruitful clinical and experimental research to determine the factors which predispose to recurrent postoperative lesions, and their possible avoidance, and has furthered the knowledge concerning the probable nature of circumscribed gastric lesions in the absence of histopathologic examination, and their capacity for temporary or permanent healing by adequate nonsurgical treatment.

Accumulating experience attests the need of thoroughness and eternal vigilance in the treatment of chronic peptic ulcer, which applies in any other chronic disease. Equally important is the elimination of physical and nervous fatigue, foci of infection, bad personal habits and proper mental hygiene wherever it is possible. With the cessation of pain and associated disturbances, there is the human tendency to grow careless, and interruption in the process of healing results, or reactivation takes place. Neither the physician nor the surgeon should entertain any conceit concerning the virtues of his particular mode of treatment under all circumstances. The former should be mindful of the invariably permanent effectiveness of timely operative intervention in the case of acutely perforated ulcer, of advanced cicatricial stenosis, of chronic, penetrating, calloused, resistant lesion, or of chronic hemorrhagic lesion, when his own efforts may have proved unsuccessful even in less formidable cases. On the other hand, the surgeon must be mindful of reactivation, or recurrences in more vulnerable situations which, although proportionately few when the patient is in competent hands, may frequently have far more serious import than the lesion for which the operation was originally done: in the past, the clinician's efforts toward possible prevention of these occurrences have more often been discouraged than encouraged.

Although the possibility of successful resection of carcinomatous lesions has slowly increased in the last few decades, such improvement has by no means been commensurate with the improved diagnostic methods and with activities directed to enlightenment of the public concerning this menace. Further progress, in spite of the indifference, procrastination or ignorance of the layman, can be made possible by both physician and specialist through cultivation of "cancer-mindedness" in the presence of those clinical situations with which one is becoming increasingly familiar.

ENDEMIC TYPHUS FEVER OF THE UNITED STATES

HISTORY, EPIDEMIOLOGY AND MODE OF TRANSMISSION

R. E. DYER, M.D.
Surgeon, U. S. Public Health Service
L. F. BADGER, M.D.
Passed Assistant Surgeon
E. T. CEDER, M.D., AND W. G. WORKMAN, M.D.
Assistant Surgeons
WASHINGTON, D. C.

As a background for a proper understanding of the problem of endemic typhus fever of the United States, we shall review briefly some of the salient details of epidemic typhus.

Epidemic typhus is known to have existed in Europe and Asia for many centuries as a disease of the lower strata of society, often afflicting great numbers of people in times of economic stress. It is a disease that has its greatest prevalence in winter and spring and shows a high degree of communicability. There are many recorded instances bearing on this latter point, but it will probably suffice to note that during the epidemic in Serbia, in 1915, the mortality among physicians in attendance in cases of typhus amounted to 36 per cent (Strong [1]).

As early as 1876, Murchison [2] stated that to prevent typhus one must protect the individual from lice.

In 1900, Moczutkowski [3] inoculated himself with typhus blood, and after a period of seventeen days typical symptoms of the disease developed.

In 1903, Cortezo [4] reported that from his experience with typhus in Madrid the disease was transmitted by lice. Nicolle, in 1909,[5] was able to infect monkeys with typhus by inoculating blood drawn from a human being at the height of the disease, and a little later [6] reported the successful transmission of typhus by body lice.

Epidemic typhus has been present in Mexico since shortly after the Spanish Conquest. Carter,[7] after thorough study, stated that "the history of the introduction of typhus into Mexico is definite, we believe, in 1526; surely in 1570." Typhus has been epidemic in the highlands of Mexico many times in the succeeding centuries. It is especially to be noted that Mexican epidemic typhus, like Old World epidemic typhus, apparently is a disease particularly of winter and spring,[8] and when epidemic, shows the high degree of communicability to be expected of a louse-borne disease.

Following Nicolle's demonstration of the susceptibility of monkeys to human blood typhus virus, Anderson and Goldberger [9] and Ricketts and Wilder [10] were able to show that monkeys were susceptible to the virus of Mexican epidemic typhus. Nicolle had been able to transmit typhus to the chimpanzee by injecting blood from human cases and from the chimpanzee to Macacus sinicus, while the American authors were able to transmit typhus fever from human cases to Macacus rhesus. Ricketts and Wilder [11] succeeded in transmitting Mexican epidemic typhus from man to monkey and from monkey to monkey by means of the body louse. This was confirmed by Goldberger and Anderson.[12]

In connection with immigration, both European and Mexican epidemic typhus have been introduced into this country from time to time. Possibly the best known instance of importation from Europe was the epidemic occurring in Philadelphia in 1836, in the study of which Gerhard [13] was able to differentiate the disease from typhoid fever. Armstrong [14] investigated an epidemic of typhus that occurred among the Navajo Indians on the San Juan Reservation in 1920 and 1921. Typhus was apparently brought to this reservation by Mexicans. An interesting instance of the importation of typhus from Mexico was noted by Boyd.[15] A total of eight cases occurred in the Santa Fe Hospital at Fort Madison, Iowa. The original case was in a Mexican who had come to Iowa from El Paso five days before the onset of sickness. A physician, three nurses and a Mexican developed typhus after being in contact with the first patient. Lice were found on both Mexicans.

Without attempting to recount the various occasions on which epidemic typhus has been introduced into the United States, it will be sufficient to state that the disease in this form apparently never gained a permanent lodging in this country.

With this understanding of epidemic typhus, we can proceed to a consideration of a form of typhus fever that is most often referred to as Brill's disease. In

1898, Brill[16] published a study of seventeen cases of a disease occurring in New York City, clinically resembling typhoid fever but without the Widal reaction. From the description of the cases in Brill's original article, and from subsequent findings, we know that these seventeen cases belonged to a mild type of typhus, although Brill did not mention typhus at that time.

In 1910, Brill[17] reported on 221 cases of this disease of "unknown origin," and the following year[18] added 34 cases to his list. In these articles Brill noted the close clinical resemblance of his cases to typhus fever. In attempting to identify this disease, he tried to infect monkeys, using blood drawn from some of his patients. In this attempt he was unsuccessful, and as a result he inclined toward the opinion that the New York disease was "in many respects different at least from the typhus fever of Mexico." In addition to the failure of his experiments on monkeys, Brill was influenced against typhus by two facts which he brought out and which were of great importance. In comparing the cases observed by him with Tunisian (epidemic) typhus and Mexican (epidemic) typhus, Brill made two statements that bear quoting:

> Nevertheless, the differences between the former [Brill's disease] and the latter [epidemic typhus] furnish important differential factors which might indicate respective individualities. There are the periods of the year in which the former [Brill's] presents itself, being most prevalent in the months of the fall, and not in the late winter and spring, which mark the appearance of typhus fever
>
> There are further epidemiological differences; these show that typhus fever is markedly communicable or contagious . . it is a fact that the disease I describe shows almost no evidence of communicability The fact obtrudes itself that, with the single exception noted in my previous contribution, no two cases of this disease have been observed by me in the same family or the same house

In 1915, Brill,[19] recognizing that the disease described by him was in reality typhus fever, stated that some other agent than the body louse must be looked for to explain the origin and spread of this form of typhus

With the discovery of Anderson and Goldberger[20] that Brill's disease was immunologically identical with Mexican typhus, it was apparently generally accepted that Brill's disease must also be louse-borne and dependent on importation from the Old World.

The flea and the bedbug had been considered as possible vectors of Mexican epidemic typhus.

Ricketts and Wilder,[10] from their observations in Mexico, pointed out that

> The season of greatest predominance of typhus in Mexico City [the spring] does not coincide with the period of greatest prevalence of the flea [summer].

They were able to rule out the bedbug as a vector by their experience with

> . . . individual cases which, it would seem, could not possibly have been carried by this insect

In a later article, these authors[21] noted that

> . . . if the bedbug transmitted typhus we should expect the disease to be a "house disease", but cases are constantly occurring which it is impossible to trace to any "typhus house"

Anderson and Goldberger,[22] on epidemiologic observations, were also able to absolve the flea and the bedbug from blame in the transmission of Mexican epidemic typhus. The observations of these authors[12] were summed up in the following words:

> All the important features of the epidemiology of typhus are satisfactorily explained on the basis of its transmission by the body louse.

The lack of epidemiologic evidence against the flea and the bedbug and the failure of attempts at experimental transmission of Mexican epidemic typhus by these insects[21] was apparently generally thought to eliminate these arthropods as possible vectors of Brill's' disease, or the endemic form of typhus fever.

Friedman[23] compared cases of Brill's disease with cases of typhus seen by him in Manchuria, and concluded that the diseases were identical clinically.

Following the recognition of Brill's disease as typhus fever, Paullin, in 1913,[24] reported six cases of Brill's disease which had occurred in Atlanta, Ga., in the months of September, October and November. In 1914, Newell and Allan[25] reported four cases of typhus fever in Charlotte, N. C. In 1916, McNeil[26] reported five cases of endemic typhus occurring in Galveston, Texas. Two of the patients were residents of Galveston, and in none could any history of probable exposure be elicited. Allan[27] reported additional cases of endemic typhus occurring in North Carolina. In this article he noted that there were no secondary cases, and that his patients were almost all of good circumstances with no evidence of infestation by lice. He also noted that he had never observed body lice on patients during fifteen years of practice in Charlotte. He expressed himself as convinced that the transmission of endemic typhus was in no way dependent on the body louse.

In 1923, Maxcy and Havens[28] reported a series of cases with a positive Weil-Felix reaction. These cases occurred during an epidemic of dengue fever, but the authors were able to differentiate them from dengue on clinical grounds. They reported eleven cases occurring in cities and towns of southern Alabama during the summer, fall and early winter. They noted that all the cases, with one exception, occurred in persons of cleanly habits and good circumstances, and that none showed any evidence of, or gave any history of, louse infestation. No source of infection with typhus could be traced. They considered that on clinical and serologic grounds their cases were most probably Brill's disease, although they were frankly puzzled by the same two epidemiologic points that had puzzled Brill thirteen years earlier—the lack of communicability and the seasonal distribution.

In 1925, Sinclair and Maxcy[29] reported cases of mild typhus which occurred in the small towns along the Texas-Mexican border in the summer of 1924. These cases corresponded closely in symptom complex with Brill's description of mild typhus. Evidence of communicability was present in the histories of six of the twenty patients examined by the authors. Body lice were not found in association with any of the cases, although careful search was made. The head louse was found to be quite common and, in view of the experimental infection of, and the possible transmission of Mexican typhus by, the head louse by Goldberger and Anderson,[12] the authors concluded that the head louse might be the vector responsible for the transmission of these mild cases in the Rio Grande Valley. During their study the authors brought out the fact that cases of mild typhus had been observed by Mexican physicians in and about the city of Monterey and the Valley States of Coahuila, Nuevo Leon and Tamaulipas. During the next few years Maxcy made an extensive study of endemic typhus in the southeastern part of the United States. In 1926,[30] he reported on 114 cases, in 41 of which he made the examination himself. His clinical description corresponds closely to Brill's description of the cases observed by him in New York City. Maxcy at this time noted that the epidemiology of the disease observed in the southern United States presented certain differences from that of Old World typhus, which were incompatible with man to man transfer by lice. In the same year, Maxcy[31] identified the disease in the southeastern part of the United States as typhus on the basis of its clinical identity with Brill's disease, the presence of the Weil-Felix reaction, the work of Anderson and Goldberger identifying the virus of Brill's disease with that of Mexican typhus, and his success (Maxcy's) in transmitting the disease to a rhesus monkey from a case in Savannah and to guinea-pigs from cases in Montgomery. He noted a seasonal distribution similar to that noted by Brill for the disease in New York City. Brill had noted that 70 per cent of his cases occurred from June to November, while over 80 per cent of Maxcy's cases occurred in the latter half of the year. Maxcy further noted that the disease did not select the poor and uncleanly and was not associated with lousiness. He found that there was a lack of traceable relationship between cases, and an extremely low secondary familial rate. Hone,[32] in 1922, described a series of cases resembling typhus fever which occurred near Adelaide, Australia. Clinically, these cases were similar to Brill's and were in men who were engaged in handling wheat. Maxcy, in his epidemiologic analysis, noted that those engaged in the handling of foodstuffs in the southeastern United States seemed to incur an increased risk of infection. From these observations, Maxcy suggested that there existed an animal reservoir of the disease other than man. As the most likely reservoir he suggested rats and mice, and as vectors some blood-sucking arthropod which would feed both on rodents and on man, such as fleas, mites or possibly ticks. Maxcy[31] suggested that endemic typhus might be carried over between epidemics in such a reservoir, occasionally being transmitted to man, and in its epidemic form being passed from man to man by the body louse. Nicolle and Lebailly[33] reported that white rats showed no fever following inoculation with Old World typhus virus, but that the virus could be recovered from the brains of these rats from ten to thirteen days later. Virus could be successfully transmitted from rat to rat for several generations. Kuczynski[34] noted that white rats produced agglutinins for B. proteus X_{19} following inoculation with epidemic typhus virus, and Mooser[35] reported a febrile reaction in white rats inoculated with Mexican typhus and that such rats developed a positive Weil-Felix reaction. Maxcy[36] found that white rats were susceptible to endemic typhus virus, and he found Rickettsia in preparations made from the tunica vaginalis of these infected animals.

In 1928, Blatteis[37] published a study of 138 cases of endemic typhus occurring in New York City between October, 1913, and August, 1927. He noted that half of these cases occurred in the four months June to October, the other half occurring during the remaining eight months. The author thought it quite improbable that the mode of transmission by the body louse is the same in endemic as in epidemic typhus.

Rumreich, Dyer and Badger[38] noted close association with rats in 78 per cent of their cases of endemic typhus.

In addition to the epidemiologic differences between Brill's disease, or endemic typhus, and epidemic typhus of the Old World, a difference has been noted in the reaction of guinea-pigs to these two types of typhus. In 1917, Neill[39] reported observations made by him on guinea-pigs which had been inoculated with strains of Mexican typhus virus. The strains of virus studied by him were obtained by Dr. Edward Francis from two cases of typhus originating in the highlands of Mexico. Neill noted that male guinea-pigs that had been inoculated intraperitoneally with these typhus strains developed a definite redness and swelling of the scrotum at the time of the febrile reaction. In the animals killed at the height of the scrotal and febrile reactions, definite hemorrhages were found in the cremasteric fascia just external to the parietal and visceral laminae of the tunica vaginalis. Sections of the testicles and epididymis showed vascular lesions, characterized by degeneration of the intima, proliferation of the endothelium and connective tissue of the vessel walls with pronounced perivascular infiltration, chiefly with cells of the lymphocyte series and of endothelial leukocytes. Neill found the changes particularly abundant in the small vessels. Thromboses were occasionally observed in the early lesions. Maxcy[40] reported that he had found the same lesions in male guinea-pigs inoculated with the endemic typhus of the Southern United States —an observation that Allan[41] confirmed. Zozaya[42] noted that many of those who have worked with Mexican typhus strains established in guinea-pigs have failed to note scrotal involvement. He suggested that this was probably due to the fact that these authors were studying typhus in epidemic form, whereas the lesions are almost exclusively found after inoculation with endemic typhus strains. Like Maxcy, he was of the opinion that endemic typhus virus, although transmitted by an agent other than the louse, can be carried on in epidemic form by the louse once a case has occurred in a human being. Zozaya further stated that in his opinion in endemic typhus two viruses were often present, and that the virus causing the scrotal reaction in guinea-pigs was not of typhus origin. That this scrotal reaction is a rarely observed reaction in guinea-pigs inoculated with strains of epidemic typhus virus recovered in the Old World is attested by many

workers. Welbach, Todd and Palfrey,[43] in describing the reaction of guinea-pigs to Old World strains of epidemic typhus virus, stated that they have not observed "reactions as striking as those described by Neill," while Olitsky and McCartney,[44] in reporting a skin reaction in guinea-pigs inoculated with Old World virus, gave a reference to Neill's work but made no observation of the occurrence of any involvement of the genitalia in the animals studied by them. That Neill's scrotal reaction does occur in certain strains of Old World epidemic typhus is attested by Pinkerton,[45] who stated that in guinea-pigs inoculated with the Wolbach strain of Old World virus he had noted scrotal reactions "entirely comparable to that seen in American typhus in four successive transfers, but it practically disappeared again in the 5th."

Nigg and Landsteiner,[46] in working with the Nicolle strain of Tunisian epidemic virus, noted that it "produced, although irregularly, scrotal inflammation of slight to moderate intensity, indistinguishable from that produced by the Mexican type." At the National Institute of Health we have maintained the Breinl strain of Old World epidemic typhus virus for several years and have occasionally noted a moderate scrotal reaction. In attempting to perpetuate this reaction in guinea-pigs, we have failed except in one instance. In the instance referred to, a guinea-pig killed on the eighth day of fever, occasioned by inoculation with Breinl virus, showed testicles covered with exudate and hemorrhages beneath the tunica. The testicles were washed in salt solution, and the washings used to inoculate other guinea-pigs. These animals, and over 80 per cent of the 154 guinea-pigs used in the succeeding 38 transfer generations, showed scrotal reactions typical of those noted in guinea-pigs inoculated with endemic typhus virus.

In 1910, Ricketts and Wilder,[47] on examining blood smears of patients with typhus fever (Giemsa strain), found small bipolar rods. They also found polar-staining organisms occasionally in ". . . the feces and intestinal contents of 'normal' lice, whereas they are present almost constantly, and often in large numbers, in similar material from 'infected' individuals (lice)."

Mooser,[48] in 1928, confirmed Neill's observations on the occurrence of the scrotal and testicular reaction in guinea-pigs inoculated with Mexican typhus and also reported the finding of diplobacilli (Rickettsia) in smears made from the tunica vaginalis of guinea-pigs showing the Neill reaction. This observation brought additional evidence of the association of the testicular lesions with typhus and of the probable rôle of Rickettsia in causation. Rickettsia in smears made from guinea-pigs inoculated with endemic typhus virus has been observed by Maxcy,[49] and from guinea-pigs inoculated with European virus by Pinkerton.[50]

Having in mind the repeated observations of the various authors cited previously, on the summer and fall incidence of endemic typhus in contrast with the winter and spring incidence of epidemic typhus, the known susceptibility of the rat to the disease, and the fact that endemic typhus occurs principally during the season when rat fleas are most prevalent, Dyer, Rumreich and Badger[51] trapped rats at three typhus foci in Baltimore. From a mixture of two species of fleas taken from these rats (Xenopsylla cheopis and Ceratophyllus fasciatus), the authors recovered the virus of endemic typhus. Endemic typhus virus was also recovered from a mixture of fleas taken from rats trapped at an endemic typhus focus in Savannah (Xenopsylla cheopis and Leptopsylla musculi).[52]

Several cases of endemic typhus had occurred on premises in the immediate vicinity of food handling establishments in Baltimore in the late summer and fall of 1930. On these premises evidence of heavy infestation with rats was observed. Rats were trapped at this place, and from them and from a rat nest fleas were recovered. Injection of an emulsion of these fleas into guinea-pigs resulted in establishing a strain of endemic typhus. Successful results followed the injection of emulsions of fleas taken from rats caught at two other typhus foci in Baltimore. A few weeks later rats were trapped at a location in Savannah, Ga., where two cases of endemic typhus had recently occurred. Rat fleas from these rats were injected into guinea-pigs, and endemic typhus developed in these animals. Both the Baltimore and Savannah flea strains were studied in laboratory animals and found to be identical with the strain of endemic typhus isolated by Maxcy[49] from a human case of the disease in Wilmington, N. C. In addition, it was noted that complete cross-immunity existed between the strains recovered from fleas and the Breinl strain of Old World epidemic typhus virus.

Mooser, Castaneda and Zinsser[53] studied an epidemic of Mexican typhus which occurred in Mexico City in April and May, 1931. During this epidemic rats were trapped at Belem Prison, their brains emulsified and injected into guinea-pigs. In two instances, the authors reported the recovery of the virus of Mexican typhus. Rather surprisingly, fleas taken from the same catch of rats from which one of their strains of Mexican typhus was isolated apparently did not contain the virus.[54]

Kemp[55] reported the recovery of the virus of endemic typhus from rat fleas taken from rats trapped at a typhus focus in Texas.

Dyer, Ceder, Rumreich and Badger[56] reported the experimental infection of fleas (X. cheopis) by feeding them on white rats infected with endemic typhus. In this experiment noninfected fleas were fed on typhus-infected rats for about two weeks. Endemic typhus virus was recovered from emulsions of these fleas. The authors also made a preliminary report of the experimental transmission of the virus of endemic typhus from rat to rat by Xenopsylla cheopis. Castaneda[57] reported the successful experimental infection of Ctenocephalus canis and Xenopsylla cheopis with the virus of Mexican typhus. Rickettsia was noted in smears made from his infected fleas, and from emulsions of other fleas which had fed on typhus infected rats he was able to recover the virus in animals.

[57] Ruiz Castaneda, M.: Med., Mexico **11:** 695 (Aug. 10) 1931.

Dyer, Ceder, Lillie, Rumreich and Badger[58] reported in detail the successful transmission of endemic typhus from rat to rat by means of the rat flea (X. cheopis). In these experiments, noninfected fleas were allowed to feed on infected white rats. The fleas were then placed on noninfected rats. Two weeks later the originally noninfected rats were killed and emulsions of their brains were inoculated into guinea-pigs. The guinea-pigs developed endemic typhus following the inoculation. The authors were also able to recover endemic typhus virus from the feces of infected fleas. They[59] reported their failure to recover typhus virus from fleas hatched from the eggs of typhus-infected fleas. They also reported that they had failed to transmit typhus by direct feeding of infected fleas on normal guinea-pigs. In these experiments the infected fleas were confined in test tubes which were closed by stretching chiffon over the open ends. The fleas fed readily through the chiffon, which kept the feces from contact with the skin, but in no instance did the guinea-pigs develop evidence of typhus, nor were they later found to be immune to subsequent injections of typhus virus. This suggested to the authors that the probable mechanism by which the flea could transmit typhus would be through the scratching or rubbing of infected flea feces into the skin. It was found by Dyer, Ceder, Workman, Rumreich and Badger[60] that endemic typhus virus remained virulent in infected fleas for at least fifty-two days after the last infective feeding. They also reported that they had succeeded in transmitting endemic typhus to guinea-pigs by rubbing and scratching crushed infected fleas or infected flea feces into the shaved skin of the abdomen. Such inoculation of fleas or feces resulted in atypical, or inapparent, infections in the guinea-pigs, but the virus was recovered readily from the brains and spleens of these animals.

Mooser and Castaneda[61] examined normal fleas (Leptopsylla musculi, Xenopsylla cheopis, Ceratophyllus fasciatus and Ctenocephalus felis) and failed to find Rickettsia. On examination of other fleas a few days after they had fed on rats infected with Mexican typhus, large numbers of Rickettsia were found, indicating to the authors that a multiplication of typhus virus had taken place in the flea. These authors made a histologic study of infected fleas and were able to demonstrate Rickettsia within the epithelial cells of the stomach and within the cells of the malpighian tubules. They noted that Rickettsia was scarce in the stomach contents of fleas, and explained this fact by the presence of a peritrophic membrane covering the cylindric epithelium of the stomach. As this membrane extends to a point immediately proximal to the union of the malpighian tubules with the intestine they were of the opinion that the number of Rickettsia eventually excreted in flea feces must depend largely on the presence of infection in the malpighian tubules. They found that the salivary glands, salivary ducts and the reproduction organs were free of Rickettsia. The absence of infection in the salivary structures may explain the lack of success of Ceder, Dyer, Rumreich and Badger in their attempts to transmit typhus by the bite of infected fleas.[59]

In order to determine if a multiplication of virus takes place in fleas infected with endemic typhus, or if the flea only hoards the virus and is in reality a mechanical vector, Dyer, Workman, Ceder, Badger and Rumreich[62] allowed noninfected fleas (Xenopsylla cheopis) to feed on infected white rats for twenty-four hours. At daily intervals they then injected guinea-pigs intraperitoneally with graded dilutions of a suspension of the ground fleas. They found that for two days after the infective feeding suspensions carrying $\frac{1}{2}$ of a flea did not contain enough virus to infect a guinea-pig, while at the end of three days suspensions carrying $\frac{1}{32}$ of a flea contained sufficient virus to infect a guinea-pig. Further titration of the virus at the end of eleven, twenty and forty days after the infective feeding showed that an infecting dose for a guinea-pig might be contained in as little as $\frac{1}{128,000}$ of a flea. The length of the incubation period in the guinea-pig became progressively shorter until the fifth or sixth day of residence of the virus in the flea. The incubation period remained approximately the same from that time until twenty days after the infective feeding of the fleas, but showed a definite lengthening in guinea-pigs inoculated with fleas forty days after their infective feeding.

The same authors[63] reported the experimental transmission of endemic typhus from rat to rat by Ceratophyllus fasciatus. In this experiment a colony of these fleas was established and proved to be noninfected. The fleas were then allowed to feed on white rats which were infected with endemic typhus. The fleas were removed from the infected rats and placed on noninfected white rats. Two weeks later the virus of endemic typhus was recovered from the spleen of one of the originally noninfected rats.

Recently we have recovered the virus of endemic typhus from the brain of a wild rat trapped at a typhus focus in Savannah, Ga.

From the foregoing facts, it would appear definitely established that the disease typhus has two manifestations known at present: the first and better known, a louse-borne disease of great communicability from person to person in times of overcrowding of unclean populations and characterized by its tendency to the formation of epidemics; the second, a disease primarily of rodents which is apparently transmitted from rat to man by rat fleas. This manifestation of typhus seemingly is not transmitted from man to man and is therefore characterized by the tendency to remain endemic.

That the endemic disease once it has occurred in a lousy population may, by transfer through lice, become epidemic in character (as suggested by Maxcy[31] and Zozaya[42]) is a possibility that must be borne in mind. Some indication that this may be true is suggested by Mooser's[64] work in successfully infecting rat fleas with epidemic typhus (Nicolle's strain) and the development of the scrotal reaction characteristic of flea-borne typhus in male guinea-pigs that were inoculated with emulsions of these infected fleas.

That endemic typhus may be kept alive in nature by the rat louse (Polyplax spinulosus) as well as by rat fleas is shown by the success of Mooser, Castaneda and Zinsser[54] in transmitting Mexican typhus fever from rat to rat by this arthropod.

That typhus virus may remain virulent in other arthropods is shown by Castaneda and Zinsser,[65] who were successful in infecting bedbugs by feeding and by intracelomic injection, and ticks[66] by the latter method. Mooser and Dummer[67] were successful in infecting body lice by rectal inoculation with endemic typhus virus but failed to infect several species of ticks by allowing them to feed on typhus-infected guinea-pigs. Dove and Shelmire[68] have apparently succeeded in infecting tropical rat mites (Liponyssus bacoti) by allowing them to feed on typhus-infected rats. Some of their experiments indicate that they were successful in transmitting endemic typhus by the bite of this mite, while in two experiments Mooser and Castaneda[61] failed to find Rickettsiae or recover typhus virus from these mites after they had been fed on typhus-infected rats. Whether the seasonal prevalence of this mite is such as to fit into the epidemiologic picture is not known. No epidemiologic facts have been uncovered in studies on endemic typhus in this country which would incriminate either the tick or the bedbug. Some confusion as to the tick existed until the past year, when it was pointed out by Badger, Dyer and Rumreich[69] and by Rumreich, Dyer and Badger[38] that some cases occurring in the eastern United States and diagnosed in past years as endemic typhus, were in reality a type of Rocky Mountain spotted fever presumably transmitted by the common tick of that region (D. variabilis).[70]

The epidemiologic features of endemic typhus—seasonal prevalence, lack of communicability, association with food handling and rat harbors, and lack of evidence against the louse—are all readily explained by the rat flea (X. cheopis). As has been noted, the rat flea (Ceratophyllus fasciatus) will also transmit typhus under experimental conditions, but the period of greatest prevalence of this flea apparently does not correspond to the period of incidence of endemic typhus as closely as does the prevalence of X. cheopis. It is thought at present that the rat flea (X. cheopis) is the common vector of endemic typhus in this country. That this may be true also for other parts of the world is shown by reports of what is apparently a mild form of typhus in other countries. In particular, it may be mentioned that Pecori[71] and Alessandrini[72] have reported a condition resembling Brill's disease which occurs in Rome in the summer and is not transmissible from man to man.

Dr. Copanaris,[73] minister of health of Greece, has stated that a type of mild typhus, occurring principally in the summer and fall, has been present in Greece for several years.

Lepine[74] reported that he has observed each year a number of cases of typhus occurring in Athens and Pireus in the absence of an actual epidemic. From the brains of rats trapped at these places he recovered a virus which is apparently similar to, or identical with, endemic typhus virus. In a more recent publication, Lepine, Caminopetros and Pangalos[75] reported the recovery of a similar virus from fleas (Xenopsylla cheopis and Leptopsylla musculi) taken from wild rats. These authors noted that the virus recovered from fleas produced in male guinea-pigs the scrotal lesions that are characteristic of Mexican typhus and endemic typhus of the United States.

ABSTRACT OF DISCUSSION

Dr. Bedford Shelmire, Dallas, Texas: It is conservatively estimated that well over 500 cases of endemic typhus fever have occurred in eastern Texas during the past three years. The seasonal and occupational incidence of the disease in this section are comparable to that reported by Dr. Dyer and his associates; yet our strain of endemic typhus seems more virulent than the strain encountered along the Atlantic seaboard. Our death rate was 4.5 per cent in 135 cases of the disease, 44 of which came under the observation of Dr. Dove and myself and the remaining 91 were reported by 21 physicians of eastern Texas during the last four months of 1931. It is not improbable that this increased virulence is due to the transmission of the typhus virus in this area by a different blood-sucking parasite. It is our belief that the virulence of the virus is stepped up by passage through the tropical rat mite. Such a difference in virulence is comparable to the two recognized types of Rocky Mountain spotted fever. It occurred to us that rats might become infected in a given area by eating typhus-infected parasites with which they were infested rather than from the bites of these parasites. When rats were experimentally infested with infected mites it was found impossible to prevent the rodents from eating the ectoparasites. As there is a known protozoan disease of rats transmitted in this manner, this route of infection cannot be overlooked. In three instances we were able to cause in these rodents a disease simulating typhus by feeding organs of guinea-pigs infected with the eastern Texas strain of the disease. In association with Dr. Kemp, feeding experiments were entirely negative when the Wilmington strain of the virus was employed. If endemic typhus fever is transmitted from rat to man through the bite of some blood-sucking parasite of these rodents, one would expect a momentary increase in the incidence of typhus following rat-poisoning campaigns. When rats are killed, their ectoparasites are forced to take blood of other warm-blooded animals or of human beings. A momentary increase was recently noted in eastern Texas following a rat-poisoning campaign, which, rodent control experts estimated, resulted in the destruction of more than a million rats.

Dr. H. A. Kemp, Dallas, Texas: In work in endemic typhus in northern Texas in the past two years I have observed a complete agreement with the significant observations in the paper just read. It is hoped that it may be of value to emphasize some of the things that have been observed. From a study of cross-immunity carried out with the Texas strain against the Wilmington strain, which was furnished through the courtesy of Dr. Dyer, there was found what I believe to be a complete cross-immunity between the virus that exists in northern Texas and the strain called the Wilmington strain of endemic typhus. Attempts have been made now for over a year to establish the virus by laboratory means and at this time I am sorry to say we have failed completely to grow this virus on any of the laboratory mediums or any of the extraordinary laboratory mediums, even the medium proposed by Dr. Kendall recently. It has also been found that a medium which is suitable for growing Bacterium tularense does not support the growth of this virus to the extent to which it grows on culture medium. In an effort to ascertain whether or not the virus was transmissible from rat to rat by any other means than through insects, rats were fed fresh material from infected guinea-pigs and at intervals of one to two, three and four weeks later these rats were killed and their brains and spleens were pooled and injected into guinea-pigs. None

of these guinea-pigs developed typhus, nor were they immune when tested later with an established strain of the virus. In other words, I feel that the insect vector is very probably the only means of transmission. A year ago an attempt was made at active immunity in endemic typhus by means of formolizing the tunica vaginalis (infected) according to the method of Zinsser. In a report recently published my co-workers and I stated that such a vaccine would immunize guinea-pigs for a period of three months against endemic typhus, against at least 300 times enough to infect them, but we found that such material did not retain its antigenic qualities even though kept in an icebox at a temperature of 9 C. for longer than thirty days.

SUSTAINED ARTIFICIAL FEVER IN THE TREATMENT OF INTRACTABLE ASTHMA

PHYSIOLOGIC AND THERAPEUTIC CONSIDERATIONS

SAMUEL M. FEINBERG, M.D.
STRAFFORD L. OSBORNE, B.P.E.
AND
MEYER J. STEINBERG, M.D.
CHICAGO

It has been observed repeatedly in the past that acute infections with fever exert a beneficial influence on chronic diseases, such as malignant conditions, dementia paralytica and others. We were especially interested in the observation that in chronic asthma and other allergic diseases the advent of an intercurrent infection, such as scarlet fever, pneumonia or an abscess, usually resulted in a temporary improvement or remission. This has been observed by others [1] and is rather common knowledge among those who treat patients with allergic diseases.

It occurred to one of us (S. M. F.) that the production of fever by artificial means might be of benefit in the treatment of chronic asthma and other allergic conditions. We were aware, of course, that there were a number of methods in use for the production of nonspecific therapy usually accompanied by febrile reactions. The intravenous injections of typhoid vaccine, intramuscular injections of milk and other proteins, injections of sulphur, use of malarial blood and similar methods were all given consideration and rejected. We felt that they were dangerous, especially in allergic patients, and that the duration and height of fever and the undesirable reactions were uncontrollable.

At that time we were not sure whether the fever itself was the active agent or whether the actual infection or the shock produced was responsible for the beneficial effect. In dealing with allergic patients we were especially anxious to evolve a method not entailing the use of foreign proteins. We were therefore led to the consideration of attempting to produce fever by physical means. Fever may be produced by hot baths,[2] hot air and electric blankets, but we rejected the possibility of using these methods because of the danger and lack of control connected with them.

We finally adopted the method used by Neymann and Osborne in the treatment of dementia paralytica.[3] Briefly, it consists of raising the body temperature by a high frequency current. We have presented earlier reports of this work,[4] and this paper deals with a larger number of patients and more extended observations.

TECHNIC

A high frequency current generator of low voltage having a capacity of 10 amperes is used. This amperage is sufficient for two patients, arranged in series (fig. 1), to be treated at the same time, and results in a material saving of time. A low voltage generator is chosen because the probability of electrical burns is materially lessened. Neymann fenestrated electrodes [5] are used with the entire trunk sandwiched between them and held in place by a canvas jacket made especially for this purpose.

Thorough heat insulation is a most essential factor in securing a satisfactory temperature curve. A method was previously described by us [6] but has now been abandoned for a simpler and far more effective arrangement. None of our patients could lie down in bed but had to recline on a back rest in the sitting or semisitting position. This made it difficult to prevent loss of heat around the shoulders, particularly when the patient became restless, and so the thought occurred to one of us (S. M. F.) that a specially prepared heat insulating bag might better serve our purpose. Such a treatment bag, designed by us (fig. 1) and made by a well known manufacturer of electrotherapeutic apparatus, is now used. The entire bag is waterproofed and so can be quite clean and sanitary. The patient is wrapped in two layers of bath blankets to absorb the perspiration, and the entire bag is closed by means of a hookless fastening arrangement (zipper type) with suitable openings for electrode leads and thermometer readings. Thus the patient is entirely enclosed with the shoulders and neck thoroughly insulated from loss of heat, no matter how restless he might become. The excessive laundry cost of the older method is reduced to an almost negligible factor by this arrangement. After use the bag can be washed without damage. Moreover, the patient is not burdened and exhausted by the weight of six heavy woolen blankets and rubber sheeting. The work of the nurse is also materially lightened.

Rectal temperature is the only safe guide. We use the thermocouple method of recording rectal temperature as this permits a minimum of disturbance to the patient and loss of heat due to getting into the treatment bag every fifteen minutes. The method and instrument used have previously been described by Markson and Osborne.[7] The difficulty of maintaining the constant junction at a constant temperature presented certain disadvantages, chief of which was an incorrect temperature reading. The problem was presented to a well known scientific supply house, and they have developed for our use a similar instrument that is simple and accurate in operation. It is a sensitive indicating device, so that the temperature changes

can be noted instantly (fig. 1). This advantage while working with high temperatures is obvious.

The care of electrodes is most important if burns are to be avoided. They must be rolled out on a flat surface, the metal free from rucks, and the rubber backing applied. The body is anointed with a lubricating jelly, and the back electrode is applied with the patient sitting up, care being taken to see that it does not extend too high at the shoulders. The canvas jacket is placed over this and the patient lies down in a position on the back rest. Then the front plate is applied but not molded to the chest by the hands. The jacket is then loosely laced down the center and is gradually tightened to a comfortable point. A gradual tightening of the side laces molds the electrodes to the body contours without digging the edges into the skin.

The amount and duration of current flow necessary to secure the desired temperature will differ with patients. We use from 3,000 to 6,000 milliamperes. Four thousand milliamperes was the general average. An hour and three-fourths was the average time necessary to secure and sustain a rectal temperature of 104 F., which it was our aim to secure and sustain for eight hours. This has been accomplished. At the end of this period insulation is gradually removed thus lowering the temperature. When the rectal temperature falls to 100 F., a tepid sponge bath is given and the patient placed in a freshly prepared bed.

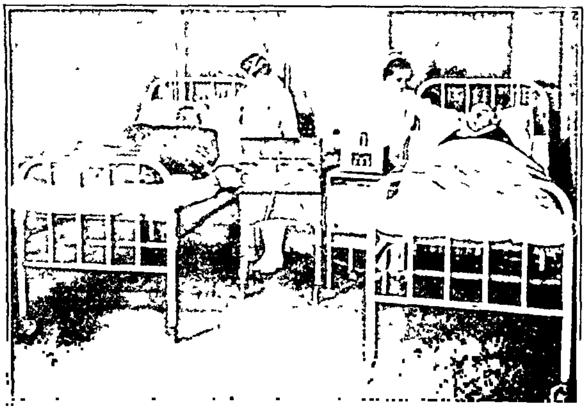

Fig 1.—Patients treated in series. The chest electrodes are coupled together and the back electrodes lead to the machine. The temperature indicator is on the table at the right.

After the current is turned off a secondary rise of temperature nearly always ensues and occasionally rises above 106 F. When the rectal temperature reaches 106 F. and a clinical thermometer is used for recording, readings should be taken every two minutes until it begins to fall. The temperature should not be permitted to exceed 106 F. rectally. At this temperature exposure of an arm is usually sufficient to prevent a further rise, and as soon as the temperature begins to drop the arm is covered again. Nurses are supplied with written instructions on methods of reducing temperature without detriment to the treatment. Occasionally the temperature will have a tendency to fall below the desired level before the eight hour period has elapsed. The use of hot water bags in the bed will often prevent this drop and may even cause the temperature to rise. Hot water bags should be removed when the rectal temperature reaches 105 F.

We have arbitrarily selected two treatments as a course, and these are given at two or three day intervals. Lately we have given repeated courses of treatment to patients when they began to retrogress. These, however, have been given at no definite interval of time.

MANAGEMENT OF THE PATIENT

Thorough examination of the patient prior to fever treatment is essential. The first object is examination and prolonged observation in order to decide whether such treatment may be necessary, as the majority of asthmatic patients will respond to the methods ordinarily used. The second object is to appraise the patient to determine whether such treatment is safe for him. A thorough physical examination, urinalysis, a blood count, electrocardiography and any other tests indicated are done to determine this point.

We have found from our experience that patients should be hospitalized for a period of from four to five days, during which time two treatments are administered. If necessary the patient may leave the hospital for two or three days between treatments. On the day of treatment the breakfast is light, the midday meal consists of fluids and in the evening a full meal may be given. During the fever the use of fluids should be encouraged; the free use of liquids does not interfere with the elevation of temperature, while the deprivation of them may make the patient extremely ill and uncomfortable.

Since there is considerable discomfort during the treatment, we have in the last few months used sedatives in practically all instances. The sedatives are administered, as a rule, at the time the patient's discomfort and restlessness become evident—usually at a temperature of 102 F. Morphine, ¼ grain (0.016 Gm.) hypodermically, is effective in most instances. In others a combination of $^{1}/_{150}$ grain (0.4 mg.) of scopolamine and from ⅙ to ¼ grain (0.010 to 0.016 Gm.) of morphine is necessary. We are also experimenting with other sedatives. In the use of sedation it is wise not to cause complete loss of sensation and not to obtain the effects too early, as otherwise burns might be produced without the knowledge of the patient. Since many patients with asthma are intolerant to morphine this drug should be used with caution. It is not at all uncommon for asthmatic attacks to occur during the fever. In most instances epinephrine is the remedy of choice.

REACTIONS

Perspiration is usually profuse. In the event of a marked diminution in diaphoresis unpleasant reactions may follow. Restlessness of varying degree is always present, the extent depending chiefly on the temperament of the patient. Nausea is present in some instances, and on three occasions vomiting resulted. In one case the vomitus contained undigested material eaten twenty-four hours previously. Muscle cramps have occurred in two or three instances, mild delirium in one and herpes labialis quite frequently, the latter, as a rule, on the day following treatment. In one instance fever persisted for three or four days following treatment, apparently due to an acute exacerbation of a chronic bronchitis.

If the pulse-rate reaches around 160 per minute, the patient should be carefully watched. If there is marked distress, a weak or irregular pulse, marked cyanosis or any other alarming symptoms the treatment should be discontinued.

PHYSIOLOGIC AND LABORATORY DATA

Our aim was to have the following data in every case in which the patient was treated: records of the rectal temperature, pulse and respiration every fifteen minutes; weight; blood pressure; vital capacity; results of urinalysis; complete blood count and the chemical composition of the blood, particularly the acid-base equilibrium, nonprotein nitrogen and urea nitrogen before and after each treatment. In addition, the blood pressure, blood count and chemical composition of the blood during the height of the fever were determined. Unfortunately, because of lack of equipment and personnel all these procedures could not be carried out often enough on a single patient to complete our data.

Table 1 shows the number of determinations we were able to make and the average results obtained. Chemical analysis of the blood showed a slight average increase of urea and nonprotein nitrogen, the largest single increases being 17.4 and 11 mg., respectively. There was practically no average increase of the carbon dioxide combining power of the blood with high fever, although in three instances there was an increase greater than 10 per cent by volume. Alkalization of the patient for a few days prior to treatment increased the carbon dioxide combining power of the plasma before treatment, but showed the usual deviation during fever. The largest single variation in these figures was either a decrease or an increase of 18 per cent by volume. In fourteen instances the change was less than 5 per cent by volume either way.

TABLE 1.—*Physiologic and Laboratory Data*

	Number of Determinations	Before Treatment		During Treatment		Average Difference During Treatment	Subsequent
		Highest	Lowest	Highest	Lowest		
Blood: Carbon dioxide combining power	74	64	38	72	35.4	−0.8% by vol.	None
Nonprotein nitrogen	40	50	27	54	27	+2.08	None
Urea nitrogen	45	44.00	9.34	45.52	10.00	+4.16	None
Blood count	60						
Hemoglobin	..	98	60	98	60	None	Improved
Erythrocytes	..	6,190,000	2,800,000	5,590,000	2,260,000	+217,000	Improved
Leukocytes	..	16,700	5,030	23,650	5,150	+2,962	Lower
Polymorphoneutrophils	..	84%	36%	94%	43%	+7.8%	Lower
Eosinophils	..	9%	Less than 1	6%	Less than 1	−1.3%	Normal
Basophils	..	3%	Less than 1	2%	Less than 1	−0.2%	Normal
Lymphocytes	..	55%	7%	46%	3%	−6.7%	Normal
Transitionals	..	14%	Less than 1	17%	0.5%	+0.7%	Normal
Blood pressure	48						
Systolic	..	146	80	176	94	+11.4	None
Diastolic	..	104	50	110	58	+4.3	None
Vital capacity	..	....	....	....	....	....	Improved
Urine	..	....	....	....	....	....	None
Weight	..	....	....	Decreased		....	Increased

There is an average increase of the red blood cells, leukocytes, neutrophilic polymorphonuclears and transitional cells. Eighteen cases showed an increase of red blood cells, while eleven showed a decrease. The average gain with fever was 217,000 cells; twenty-two showed an increase in leukocytes and seven a decrease, the average gain being 2,962 cells. The eosinophil percentage decreased noticeably during the fever, but subsequently returned to its former range.

The blood pressure readings indicated a moderate rise in systolic and a slight rise in diastolic pressures. In a previous communication on fever therapy it was indicated that the systolic pressure rose and the diastolic fell during the height of the fever. We believe that the change in our data recently has been due to the medication in the form of morphine sulphate or morphine and scopolamine which the patients have been receiving during the treatment.

There was a loss of from 2 to 5 pounds (0.9 to 2.3 Kg.) with each treatment, chiefly from the profuse diaphoresis. This was rapidly regained in one or two days. The majority of patients gained weight as a result of improvement in their general health.

In those instances in which we were able to check up on the vital capacity before and after successful treatment there was found an increase of as much as 2 liters.

Aside from the increase in vital capacity and weight there were no decided subsequent changes in the chemical composition of the blood and the blood pressure.

SELECTION OF CASES

All of the patients selected for treatment were those who had failed to respond to all the usual methods, and most of them had been under our care for from a few months to several years. They were all suffering with chronic asthma, one or more attacks occurring daily, and the majority of the attacks were severe. About 70 per cent had one or more complicating pulmonary conditions, such as emphysema, marked bronchitis and peribronchitis and bronchiectasis. Two patients had active syphilis.

ANALYSIS OF RESULTS

The results are tabulated in a way to indicate the history of the patient with respect to age, sex, duration, complications, final diagnosis and treatment up to the time diathermy fever was used as a method of therapy (table 2). Under previous treatment we mean to include a complete diagnostic appraisal with history, physical examination and complete laboratory data. All cases were thoroughly tested from the standpoint of hypersensitiveness. Removal of atopens when possible, prolonged attempts at desensitization, autogenous and stock vaccines, physical therapy, roentgen exposures, injections of sulphur, intravenous injections of sodium iodide, acid mixtures and other measures were utilized in attempting to benefit our patients. Surgical procedures, especially about the nose, throat and accessory sinuses, were carried out in many instances. We have included the dates of the first and the last treatments, the period of observation and the results. When the patient has been absolutely free from asthmatic attacks we have designated this as remission; when the symptoms have been definitely diminished we have designated it as improvement. We have arbitrarily decided on a temperature of 103 F. or more sustained for at least five hours as a satisfactory treatment, and less than this as unsatisfactory treatment. During the past few months, owing to improved technic and better equipment, we have been able to maintain a temperature of 104 F. or more continuously for eight hours without marked discomfort or danger to the patient (see temperature curve [fig. 2]).

SUMMARY OF RESULTS (TABLES 2, 3 AND 4)

Since a previous communication, twenty-five additional patients, or forty-two in all, were treated. In addition, some of those previously treated received further treatment. Only thirty-seven cases have been tabulated, five having been omitted because of insufficient data. This was necessitated by several factors. In some instances the patients received one or two treatments and were not heard from thereafter. In others the treatment was so unsatisfactory as to be valueless; these were cases in which the temperature was hardly elevated, owing chiefly to lack of cooperation by the patient. One patient who was treated only a week ago is in a remission.

TABLE 2.—*Analysis of Cases Treated*

Twenty-one patients received at least one satisfactory treatment, the largest number of such treatments in a single case being eight, and the least, one. Fifty-six satisfactory and sixty-five unsatisfactory treatments were given in all. The longest period of observation was fourteen months, in two cases; it was from twelve to thirteen months in five cases. Six cases were observed for one month or less. Nineteen cases showed complete remissions, varying from four to two hundred and eighty-five days. In three instances the remissions have not ceased to the time of writing. Thirty patients have shown distinct improvement, varying from fourteen to three hundred and thirty days. Twenty-two patients have shown improvement for a month or more. No average days of remission or improvement per case can be estimated in all instances as several of the patients are still in remission or continue to be markedly improved. Not one patient who received three or more satisfactory treatments failed to respond with improvement. Nine of twelve allergic patients showed either remission or improvement. Treatments were usually given in pairs three days apart. Eighty per cent of the patients treated showed remission, improvement or both; 13 per cent were unimproved.

COMMENT

Since our first publication[5] on fever treatment of asthma there have been reports by others indicating poor results with such treatment. Analysis of the protocols of these cases makes it evident that the fever in the majority of the reported cases was not kept high enough for a sufficient length of time. To our mind this is sufficient reason to account for their failures, since our own results have even improved over those of our first reports by giving more thorough treatment.

Our series of cases included both nonallergic and allergic patients, but mostly the former. The allergic cases were, however, also complicated by bronchial infection. Apparently, the percentage of success in the cases of allergic and nonallergic asthma was about the same. In the group of allergic patients we had the opportunity of making quantitative studies on the skin and on the atopic reagins, before and after the fever treatments. We found no decided changes in that direction and were forced to conclude that the mechanism of relief could not be explained on that basis. Figures 3 and 4 show examples of such studies.

There are many other possibilities which might be considered as an explanation of relief of asthma by fever treatment. It has been claimed[8] that asthma (and other allergic conditions) is a state of potential alkalosis and that anything which increases the acidity will relieve the asthma. In support of that theory the exponent cites a number of conditions accompanied by acidosis, among which is infectious fever, that have a beneficial effect on allergic manifestations. In our work we found that artificial fever caused a negligible decrease in the carbon dioxide combining power of the plasma, in some cases even an increase occurred. We realize that more extended chemical examinations would have to be made to settle this problem, but we think that no marked changes in acid-base balance occur. In these observations we are supported by the findings of others in artificial[9] and natural fevers.[10] We went a step further and proceeded to alkalize several patients prior to treatment and found that it in no way prevented a successful outcome. Antibody responses cannot be offered at present as the mechanism involved, if we are to be guided by the lack of increase in complement and opsonins.[11] The increase in leukocytes, while usually present, was only moderate.

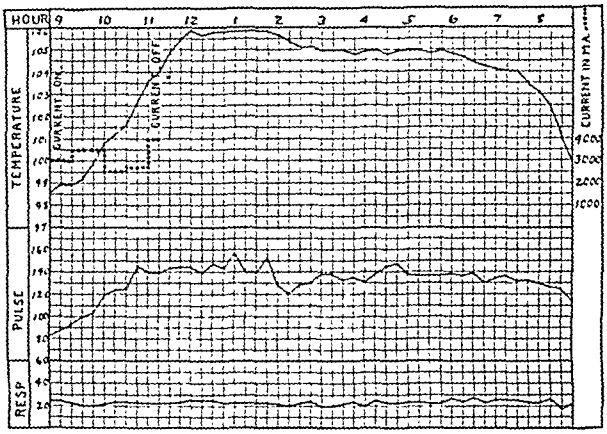

Fig. 2.—Typical fever curve obtained with high frequency current in an asthmatic patient.

It has been suggested[12] that the curative value of fever and inflammation from nonspecific agents owes its origin to split protein products and not to the fever. In a fever produced by physical means such products are, of course, least likely to be present. The possibility of increased capillary permeability with resulting local increase of antibodies or perhaps improved conditions for absorption of inflammatory products must be considered. This thought is supported by the work of Mehrtens and Pouppirt,[13] who found an increased permeability of the meninges following fever produced by baths.

The well known effects of heat and fever on the vascular bed and consequent improved conditions for absorption of inflammatory and waste materials may be offered as an explanation for the results of fever treatment in asthma. In the same connection it might be argued that the effect of the fever may be to stimulate the sympathetic nervous system, thus resulting in bronchial relaxation. It would be difficult to see, however, why such an effect would be prolonged.

Another suggestion for a possible mechanism for this effect lies in the work of von Euler,[14] who found in the blood of patients with fever some substance having the properties of epinephrine. The effect of fever on the reticulo-endothelial system also requires consideration.

Since Duke [15] has suggested that patients sensitive to heat may be relieved by heat, it might be argued that our patients obtained their effects on this basis. It is hardly probable, however, that the majority of our patients were sensitive to heat.

The effect of fever treatment on other allergic conditions has been considered by us. In several instances of seasonal hay fever we have obtained encouraging results. In a woman with chronic urticaria of long standing we obtained a remission of two weeks with further improvement as a result of a single treatment. In one case of asthma associated with chronic eczema there was improvement in the latter condition. However, in none of the allergic conditions outside of asthma has our experience with fever treatment been sufficient to warrant any definite opinion.

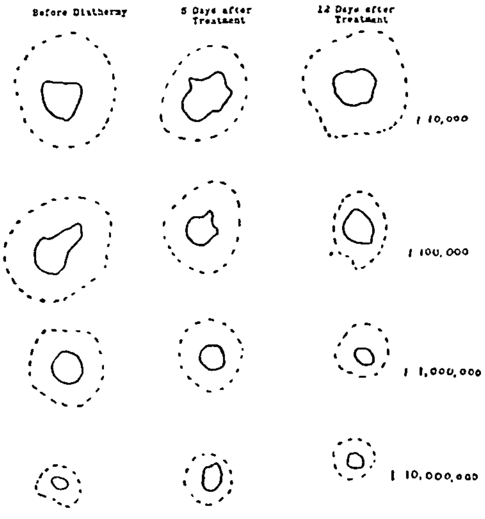

Fig. 3.—Effect of diathermy fever on skin tests. Intradermal tests with dilutions of wheat in J. W. (case 6, table 2).

SUMMARY

This report concerns a group of forty-two patients with intractable asthma, 70 per cent of whom had complications such as emphysema, chronic bronchitis or bronchiectasis, and all of whom had been unrelieved by the usual methods of treatment. Fever, produced by high frequency currents according to a described improved technic, was tried in all of these patients and was found to be a safe procedure. Of thirty-five of those in whom the results have been ascertained, 51 per cent had a complete remission varying from several days to nine and one-half months, and 29 per cent had improvement without remissions.

It is possible that with cases of milder degree and with more persistent treatment even better results may be obtained. The laboratory determinations and other observations do not as yet allow any conclusion as to the mechanism of this relief. It is suggested that fever therapy may possibly be found useful in other allergic conditions such as urticaria, angioneurotic edema, eczema, hay fever and migraine.

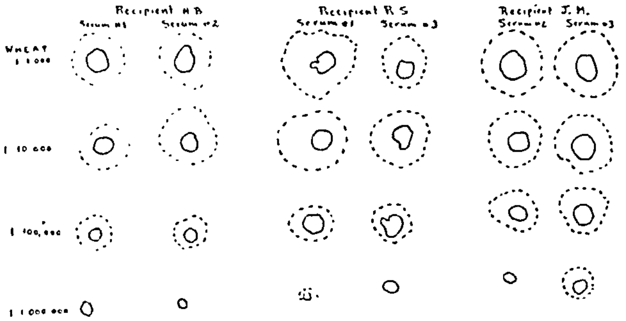

Fig. 4.—Effect of diathermy fever on reagin. Intradermal tests with dilutions of whole wheat on the skins of three persons sensitized with the serum of J. W. The reactions under Serum 1 were before treatment; those under Serum 2, at the height of fever, and those under Serum 3, five days after treatment.

In conclusion, we may definitely state that in fever therapy we have found a method of obtaining relief in some cases of intractable asthma in which all other methods had heretofore failed.

PATHOLOGY AND SYMPTOMATOLOGY OF HEADACHES DUE TO SPECIFIC SENSITIZATION

HERBERT J. RINKEL, M.D.
AND
RAY M. BALYEAT, M.D.
OKLAHOMA CITY

Headaches due to specific sensitization with the clinical characteristics of migraine have been reported by a number of authors.[1] The term "migraine," as commonly used,[2] in the main refers to paroxysmal attacks of hemicrania (occasionally bilateral headache) associated with sensory and motor disturbances. These motor and sensory symptoms, as well as the crossed hemicrania, gastric and cardiac inhibition and vasomotor

changes, indicate disease of the cerebral cortex.[2d] Thus migraine may be defined as a paroxysmal disease characterized by hemicrania (also bilateral headache) and symptomatic evidence of cortical involvement.

There are headaches due to hypersensitiveness that cannot be classified as migraine since they do not have cortical features. Eyermann[3] called attention to this and suggested the term "allergic headache" instead of "allergic migraine." Some headaches have clinical phenomena that indicate their allergic nature, but many, including migraine, do not. That any symptoms are due to allergy must be determined by clinical trial, i. e., relief by avoidance and recurrence on contact or ingestion. All headaches that are due to specific hypersensitiveness (allergy) should be designated as such, and the particular form indicated, i. e., migraine, the bandlike headache of hay fever, frontal sinus headache, etc.

For the purpose of study an analysis of sixty-five such cases is presented (table 1).

These sixty-five cases were selected because in each instance headache had been produced by ingestion of foods, relief by dietary manipulation alone had been excellent and, in addition, the history as given by the patient was satisfactory.

Several points are worthy of mention. 1. The attacks are longer, though less frequent, in females, while males have frequent attacks of shorter duration. 2. Attacks with prodromal symptoms, sensory, motor and vasomotor phenomena, hemicrania and a postmigrainous phase were reported by approximately one half of these patients. 3. Hyperactivity, either physical or mental, is twice as common in women as in men. 4. The menses are the most frequent predisposing factor in woman and physical exhaustion is in man. 5. Familial headache occurs in a ratio of 3:1 to allergic diseases. 6. One third of these patients knew that certain foods produced their present complaint.

[3] Eyermann, C. H.: Allergic Headache, J. Allergy **2**: 106 (Jan.) 1931.

A patient who has bilateral headache with aura and who also experiences a unilateral attack with sensory and motor symptoms is listed in the latter group. We consider hemicrania with premonitory phenomena, aura, signs of exhaustion, etc., as the most important clinical form. The generalized headache with the same features is thought to be second in importance. Symptoms manifest in various attacks vary greatly, as can be seen in table 3.

Table 2.—*Analysis of Symptomatology of Sixty-Five Patients with Headache Due to Specific Sensitization*

Patients in Whom the Majority of Symptoms Were	Females		Males	
	No.	%	No.	%
Hemicrania with prodromata, aura and a postmigrainous phase	18	54.54	16	50.0
Hemicrania, aura and postmigrainous stage	3	9.09	5	15.62
Hemicrania with aura	1	3.03	0	
Hemicrania without prodromata, aura or postmigrainous symptoms (all attacks)	0		2	6.25
Bilateral headach, each attack with prodromata, aura and postmigrainous stage	7	21.21	4	12.50
Bilateral headache, each attack with aura and postmigrainous stage only	0		2	6.25
Bilateral headache, each attack with aura alone	1	3.03	1	3.12
Bilateral headache, always without aura	3	9.09	2	6.25
Total	33	99.99	32	99.99
Frontal headache with nasal congestion was present in	4	12.1	6	18.7
It was associated with prodromata, aura, hemicrania and postmigrainous phase in	3	9.09	3	9.3
It was associated with bilateral headache, prodromata, aura and postmigrainous phase in	1	3.03	2	6.25
It was associated with bilateral headache, aura and postmigrainous phase in	0		1	3.12

This variation is significant from the standpoint of both history taking and pathology. The patient is apt to describe his severest symptoms, and therefore may stress any one of these various types. From the standpoint of pathogenesis it is apparent that such a wide variation in symptoms in the same patient is probably not due to one localized organic lesion.

Unilateral or bifrontal headache is experienced by many patients, especially those with perennial vasomotor rhinitis. These patients in the main obtain immediate and complete relief when the nasal congestion is properly treated. In the majority of patients the instillation of ephedrine inhalant is sufficient. The pain results from closure of the nasofrontal duct, either by pressure or by pathologic swellings within the duct. It is made worse by using the eyes.[4] In one patient unilateral or bifrontal headache with nausea and emesis occurred every time she attended the theater. She was sensitive to orris root, and after desensitization had no further trouble. Headache due to pressure of the turbinates on the septum should not be confused with this type.

Table 3.—*Variation of Symptoms in Different Attacks in Eighteen Females and Sixteen Males*

	Females		Males	
	No.	%	No.	%
Patients with prodromata, aura, hemicrania and postmigrainous phase in the majority of instances	18	54.5	16	50.0
They also experienced				
Hemicrania with aura and postmigrainous phase only	8	24.2	7	21.8
Hemicrania with aura alone	4	12.1	4	12.5
Hemicrania without sensory, motor or vasomotor symptoms	1	3.03	7	21.8
Bilateral headache with prodromata, aura and postmigrainous phase	7	21.2	11	34.3
Bilateral headache with aura and postmigrainous stage	1	3.03	6	18.7
Bilateral headache with aura alone	0		1	3.12
Bilateral headache without sensory and motor symptoms	1	3.03	5	15.6
Frontal headache with nasal congestion	3	9.09	3	9.3
Headache due to sinusitis, secondary to nasal allergy	1	3.03	1	3.12

Patients with seasonal hay fever often experience a bandlike headache. The swelling of the mucosa lining the sinuses and nasal fossae results in pain, because of either pressure or interference with drainage. Headache occurring with the systemic reaction of pollen therapy, blood transfusion and drug therapy has been reported by Duke.[5] In our studies cortical features were not observed in such cases.

In one case, headache as a result of acute maxillary sinusitis has been reduced from five to six attacks each year to one in two and one-half years, by treating the existing hypersensitiveness. Sensitization is so frequently a predisposing factor in sinus infection that we mention it at this time. The headache is not due to allergy.

Table 4.—*Incidence of Familial Headache and Other Allergy in Sixty-Five Patients with Various Types of Headache*

Symptomatology	Females			Males		
	Number	Per Cent of Type	Per Cent of Total	Number	Per Cent of Type	Per Cent of Total
Hemicrania with either prodromata, aura or postmigrainous phase	22	.....	66.66	20	.....	62.50

History of other allergy	6	55.0	18.18	5	55.5	15.62

THE FAMILY HISTORY

A family history of headache was obtained in twenty-eight (84.4 per cent) of the women and twenty-three (71.8 per cent) of the men. The average age of onset for patients with a bilateral family history of allergy was 7.01 years in females and 10.5 years in males, whereas with a unilateral family history symptoms began at 13.9 and 12.4 years respectively. This indicates that heredity determines not only the clinical form of hypersensitiveness but the age of onset.[6]

From these data it appears that patients with unilateral headache have a higher incidence of familial headache, whereas those with bilateral attacks have a higher incidence of other allergy. Until a larger group of cases are studied, no definite conclusions should be drawn.

Headaches due to food or inhalants may be classified according to symptomatology under the following headings:

- I. Migraine
    - *a.* Hemicrania with prodromata, aura and postmigrainous phase; also those attacks having only aura and postmigrainous phase, or aura alone
    - *b.* Bilateral headache with prodromata, aura and postmigrainous phase; also with aura and postmigrainous phase, or aura alone
- II. Headache always without sensory, motor or vasomotor symptoms
    - *a.* Without nasal pathology
    - *b.* With nasal pathology
        - (1) Frontal headache
        - (2) Headache associated with seasonal or perennial vasomotor rhinitis
    - *c.* Headache of allergic reaction

The recurrence of attacks is subject to wide variation, and we believe that important information may be obtained by a careful study of the frequency.

- I. Periodic
    - *a.* Occurring
        - (1) Only in association with the menses
        - (2) Before puberty and after the menopause
    - *b.* Occurring at regular intervals (i. e., from fourteen to twenty-one days)
        - (1) Etiology not determined
        - (2) Etiologic factor demonstrable; headache due to periodic ingestion of the specific factor
    - *c.* Seasonal
- II. Nonperiodic
    - *a.* Occurring at irregular intervals
        - (1) With each ingestion of one or more foods
        - (2) After repeated ingestion of one or more foods
        - (3) Attacks precipitated by predisposing causes
            - (*a*) Emotional stress
            - (*b*) Anger
            - (*c*) Genitosexual
            - (*d*) Constipation
            - (*e*) Thyroid dysfunction
            - (*f*) Physical fatigue
            - (*g*) Mental fatigue
            - (*h*) Disturbance of special senses
    - *b.* Chronic form of headache (status migrainous), secondary to paroxysmal attack
    - *c.* Headache occurring always with, but also between, menses

The consideration of recurrence is important because it gives a clue to factors other than those of sensitization. A patient whose attacks occurred only at the menstrual period presented a different diagnostic problem from one whose difficulty occurred before puberty and after the menopause, and was still different than the one whose attacks recurred every fourteen days regardless of dietary manipulation. In the latter case food could induce a headache clinically the same as that occurring at periodic intervals. This periodicity may be due to the mode of living. There were two men whose weekly attacks over a period of years, were caused by foods taken on Saturday and Sunday but not used at any other time.

Some cases had seasonal features; i. e., attacks were limited to certain months of the year. Again, patients would have attacks over a period of six or eight weeks and then be free for no apparent reason for from twelve to fourteen weeks. Mitchell[7] has also reported this seasonal variation.

Of the nonperiodic headaches, the one most amenable to treatment occurs after each ingestion of a particular food. Therefore, the incidence is irregular.

Attacks may result from a single ingestion of a food, or occur with repeated taking of the same food; that is, the patient will have difficulty a week or ten days after a food is used in his diet. The symptoms are apparently the result of a cumulative action. Many patients state that their symptoms occur in definite relation to one or more of the predisposing factors. Fatigue, emotional stress and the menses are the most common. In one case an attack with prodromata, aura, hemicrania and a postmigrainous stage was definitely related to fits of anger. In this same patient headache could be produced at will by the ingestion of certain foods.

The chronic form of headache secondary to paroxysmal attacks may be confused with tumor of the brain, syphilis or uremia. It has been much more difficult to relieve these patients, although results have been obtained.

Women whose headache occurs with, but also between, the menses, have been considered as a separate group. It appears that other factors, as well as sensitization, are of etiologic importance.

Classification on the basis of (1) symptomatology and (2) recurrence is of value in arranging therapeutics. The prognosis seems best in those cases that have the clinical features of migraine, and recurrences are nonperiodic and occur after each ingestion of the food to which the patient is sensitive.

Where one deals chiefly with subjective symptoms, the chances of error and misinterpretation are many. We report these findings, fully cognizant of this fact, and with the hope that they will stimulate further study of this clinical phenomenon.

PATHOLOGY

Frontal sinus and band-like headaches of hay fever are due to various degrees of swelling and exudation in the mucosa and adjacent structures, such as swelling of the turbinates, resulting in pressure on the nasal septum or obstruction to the natural drainage, for instance, closure of the nasal frontal duct.

The pathology of the headache of systemic allergic reaction is probably due to similar changes.

We have not been able to demonstrate pathologic changes in patients who always have unilateral or bilateral headache without aura. In a number of these there was nasal congestion, chiefly after the headache, and when it was present during the attack, treatment of the congestion did not bring relief.

In discussing the pathology of the unilateral and bilateral headache with sensory, motor and vasomotor symptoms, we deal chiefly with theories and associated findings. Migraine refers to a clinical and not a pathologic entity. It may result from syphilis or malaria,[7] as well as from tumor of the pineal gland,[8] changes in the meninges[9] and tumefaction involving the third nerve. It is for this reason that complete details of the attack are of such great value.

An acceptable theory of pathology must take into consideration the frequency and age of onset, the influence of the vegetative nervous system and the frequently recurring attacks which leave no symptomatic evidence of permanent change. It is most certain that errors of refraction, nasal disease and pituitary enlargement can cause paroxysmal headache, but paralysis of cortical cells or symptoms of irritation are not likely to be manifest. Scintillating scotomas are not produced by irritation to the optic nerve distal to the geniculate bodies.[10] This would rule out suprasellar cysts and adenomas of the pituitary body. It is quite possible for these conditions to cause hemicrania, but this is not synonymous with migraine.

If there is any evidence of involvement of the central nervous system with an infected sinus it will be that of meningitis or abscess of the brain, not scintillating scotomas, hemianopia, zigzag lights, motor aphasia or paresthesias. The same is true of errors of refraction.

ASSOCIATED PATHOLOGIC CHANGES

Cytologic studies were made in fourteen patients between, and two during, attacks. Three of these had other allergy. The results are shown in table 5.

TABLE 5.—*Cytologic Studies in Fourteen Patients Between, and in Two During, Attacks of Headache*

Case	Sex of Patient	In	Out	Other Sensitization	Myelocytes	Metamyelocytes	Band	Segmented	Total	Lymphocytes Small	Lymphocytes Large	Lymphocytes Total	Monocytes	Eosinophils	Basophils	Nuclear Index	White Blood Cells	Hemoglobin

The significant change in neutrophils was 31.25 per cent neutrophilia. Lymphocytosis occurred in 50 per cent of the cases. Monocytes showed a decrease in 37.5 per cent of the cases, eosinophilia an increase in 37.5 per cent and basophils an increase in 25 per cent of the cases The most important single change in the blood was a lymphocytosis. Monocytes, eosinophils and neutrophils changed about equally.

The average free acidity was 25.6 in twelve males and 24.8 in seven females. The combined acid was 37.3 and 20.2 respectively, while the total was 62.1 and 45.8 The average weight of the females was 123 pounds (55.8 Kg.) and that of the males 154 pounds (69.8 Kg.), while the average height was 64.25 inches (163.1 cm.) and 67 48 inches (171.4 cm) respectively. The weight of one of each sex exceeded 175 pounds (79.3 Kg.). The average weight for an age group of this height is 135 and 152 pounds (61.2 and 68.9 Kg.), according to life insurance statistics. Moehlig[11] has called attention to the average height in the family history. We have not made a detailed study of the height other than in the patient.

The basal metabolism test was made in twenty-two females and nineteen males. An average of plus 4 was obtained in two females and plus 9.5 in seven males. Twenty female patients averaged minus 14 and twelve males averaged minus 14 4.

Passive transfer was made according to the technic of Prausnitz and Kustner.[12] In case 1 the blood serum was from a patient who had migraine symptoms from chocolate, wheat and milk, while the patient in case 2 experienced hemicrania, paresthesias and exhaustion after ingesting potato, banana and egg. In both cases intracutaneous tests were run in the sensitized area twenty-four hours later, using 0.02 cc. of the food extract. Definite reactions were obtained with chocolate, wheat and milk in the areas sensitized with the serum from case 1. Potato and egg extracts gave definite reactions in the areas sensitized with the serum from case 2. The reaction with banana was positive, but the control injection also gave some reaction. The other control tests were negative. The banana extract has a tendency to cause nonspecific reactions, and it is possible that transfer was accomplished.

Ophthalmoscopic examination of the fundus and retina revealed no changes in attacks as compared with periods of freedom.[13] In two cases examination was made after headache of five days' duration. Both patients were subject to practically continuous headache for several months and had definite visual symptoms.

There was an average elevation of blood pressure of 30 mm. of mercury in three females and one male during the headache. In three women and three men it remained normal, while in one patient of each sex it was reduced. The results obtained in treatment were better in those with elevated blood pressure. In patients with chronic headache there was no change from their normal blood pressure. The average blood pressure in millimeters of mercury out of attack was 124 systolic and 80 diastolic in both sexes.

TABLE 6.—*Summary of Cytologic Studies in Sixteen Cases of Headache* *

		Per Cent	Per Cent In	Per Cent Out
Neutrophils	Normal	68.75	36.36	63.64
	Decrease	31.25	0.0	100.0
Lymphocytes .	Normal	50.0	37.5	62.5
	Increase	50.0	12.5	87.5

CONCLUSIONS

An analysis of the symptomatology and associated pathologic changes in sixty-five patients in whom headaches could be induced by clinical trial reveals:

1. In approximately 85 per cent of the patients the headaches were characterized by prodromata, aura, unilateral or bilateral headache and a postmigrainous phase of exhaustion, sleepiness, polyuria or nasal symptoms.
2. The term migraine implies a clinical, not a pathologic entity, and should be used as such, and the specific cause of the attack should be stated, when known.
3. There is a wide variation of symptoms in the same patient, in different attacks.
4. The familial history of the headache is approximately three times as frequent as is the history of any allergic disease.
5. Headaches due to specific sensitization may be classified according to symptomatology as (*a*) migraine and (*b*) headaches without sensory, motor or vasomotor changes. The latter group includes (1) headaches without other demonstrable pathology, (2) attacks associated with allergic reactions in the nose and sinuses, that is, frontal and other headaches occurring in patients with seasonal or perennial vasomotor rhinitis, and (3) the headache of general allergic reaction. According to recurrence they may be classified as the periodic and nonperiodic.
6. The findings obtained by gastric analysis, basal metabolism, cytologic study and ophthalmoscopic examination have not been of diagnostic value. The weight and height average of these patients was within the normal limits.
7. Passive transfer was accomplished using the technic of Prausnitz and Küstner.
8. From these studies it appears that the symptomatology, familial history and protean manifestations of headaches due to specific sensitization are similar to those of hereditary migraine.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. FEINBERG, OSBORNE AND STEINBERG AND DRS. RINKEL AND BALYEAT

Dr. Milton B. Cohen, Cleveland: I agree that this examination of the nasal smear or of the sputum smear is of some importance in the diagnosis of the case that is on the borderline between allergy and some infection. I have a slide showing the histology of an allergic wheal in human skin removed thirty minutes after the injection of ragweed pollen extract into the abdominal wall of a man sensitive to ragweed. One can see the great number of eosinophils that have appeared in the tissue within this thirty-minute period. If one has this great number of eosinophils in the tissue, in a characteristic allergic reaction, one expects that the fluids exuded by this tissue will contain eosinophils. I believe that this is the explanation for the presence of eosinophils. Dr. Kline of Cleveland and my other associates have made a study of the cellular reaction in specimens removed for histologic study, from ten minutes to twenty-two hours after the production of an allergic reaction. It is interesting to note that within ten minutes there are only a few eosinophils present, that they rapidly increase, reaching 90 per cent of the cells present in the differential count, within about thirty minutes, and that they have practically disappeared in three hours. There are only a few cells at ten minutes, but 90 per cent are polymorphonuclear neutrophils. One will notice that the count of these drops, when the eosinophils go up, almost to nothing. But, again, at the end of the three hours there is a tremendous rise in polymorphonuclear neutrophils, and they remain high. One will notice also that the mononuclear cells which are not present at all come in so as to phagocytose the débris which is produced by the inflammatory reaction. Therefore, if this test is to be useful, one must get smears shortly after the patient has made the contact with the substance that is going to produce the reaction.

Dr. George Piness, Los Angeles: I want to congratulate Dr. Balyeat on his change of attitude toward migraine, in that in his former papers he considered all migraines from an allergic basis. Today he discusses this type of headache as being an allergic headache. I believe there is a definite distinction between migraine and allergic headache. There is little known about the pathologic changes in migraine and until such time as pathologic material is available one will be unable to discuss these changes clearly. I should like to ask Dr. Balyeat how one can determine from a history whether an individual is sensitive to foods and detect sensitivity from the history alone. It has always been my experience that the physician's guess is no better than the patient's and that is a poor one. I think it is advisable, and certainly more satisfactory, to resort to specific methods and means of determining etiology. Another point is that food allergy per se is rare; in a recent study of 7,000 cases, only 1 in 100 individuals reacted in such a manner. It is difficult for the trained allergist to believe that migraine can be cleared up by the elimination of foods alone. Dr. Feinberg's results as presented today seem less satisfactory than those reported last year. He fails to mention that Dr. Leopold of Philadelphia and I at Los Angeles reported practically 100 per cent of failures and by failure we mean that the patient did not receive any degree of permanent relief as a result of this drastic treatment. The theory of the hyperthermia treatment is based on the fact that, in our observation over many years, patients having intercurrent diseases of an infectious nature in which fever was present were usually free of their asthma. Then with the work on dementia paralytica in which temperature was the therapeutic measure we decided that perhaps there might be some relation between the type of temperature produced by hyperthermia and that of infectious diseases that produce increased temperature, and that relief might be given to the person with chronic intractable asthma. Therefore a series of patients was treated in a similar manner to that described by Dr. Feinberg, with rather interesting results. The patient's temperature was elevated to 102 or 106 F. and sustained at that point for several hours. However, the results did not warrant continuation of the treatment. We concluded, therefore, that the temperature in acute infectious disease was due to nonspecific protein reaction which gave the relief and was not the result of hyperthermia produced by the high frequency method. Therefore the reactions are quite dissimilar. I do not feel that a remission of two days or even twenty weeks is evidence of cure or improvement. It is not an uncommon occurrence for the patient with even the most intractable asthma to have such a period of freedom with or without any treatment. I should consider his interpretation of results as merely an arbitrary one chiefly because any new form of treatment in the chronic sick will psychologically cause the patient to think he has improved.

Dr. M. Murray Peshkin, New York: Because patients with asthma are known to become free from symptoms following an intercurrent infection, accompanied by fever, and because the artificial induction of fever in allergic patients following the injection of various substances temporarily relieves asthma occasionally, diathermy is therefore selected by Dr. Feinberg as the most suitable method for the induction of sustained fever in the treatment of asthma. The impression is gained that the good results reported by Dr. Feinberg are solely dependent on the fever and that the fever parallels in many ways the fever induced by intercurrent infection or that induced by injection of nonspecific substances. There is insufficient evidence to corroborate this assumption. One thing is certain, the patient has fever by whatever means. Extensive clinical experience has taught that the mechanism behind the fever induced by the injection of various substances is not the same as that induced by natural means (intercurrent infection). The relief from asthma by the latter method is also temporary but lasts for longer periods. The induction of sustained fever by mechanical means is recommended by Dr. Feinberg to replace the injection method, minus the so-called dangers of the latter method, in spite of the fact that the nonspecific injection method of treatment is more direct and more closely parallels the workings of the defensive mechanism brought to play by the fever associated with intercurrent infection. The results at the best, with either method, are only temporary and disappointing. It is apparent that it is not the fever itself that brings about the temporary relief. In other words, the fever is only an incidental phase in the whole picture. Dr. Feinberg treated this group of asthmatic patients with sedatives also. I should like to know whether he has also continued the restriction of all other methods of treatment which he previously employed, to the induction of this sustained fever treatment. Much to my surprise, he speaks of various untoward symptoms which, when alarming, indicate that one should discontinue this so-called harmless diathermy treatment. Finally, it should be borne in mind that various nonspecific substances have also been used without the induction of fever and have also brought about some fairly good results.

Dr. Alfred M. Goltman, Memphis, Tenn.: The cellular theory of allergy as advocated by Kolmer and others is the one that is accepted at present, but one should not forget that all allergic reactions or symptoms, so to speak, are produced through the autonomic nervous system and the end-result is a localized or general cellular reaction. Now, it is a fact that in old asthmatic patients the chest serves as a focus of infection, which may be dormant or active. When increased temperature is produced, as by diathermy, activity in the chest is increased; toxin production is increased. This serves as a sedative or poison to the autonomic nervous system, so that it is not so highly irritable and, therefore, bronchial spasm and the like from this source is greatly diminished. Individuals who are asthmatic and develop acute infectious diseases are relieved in many instances of their asthma and the relief may last for months. Is it due to the fever? I doubt it. It seems to me that it is more likely due to the toxins of the disease and their secondary effect either on the autonomic nervous system or on the body cells themselves. Recently I observed an epidemic in children in whom the postauricular lymph nodes were swollen and tender at first. After two days the children would develop a generalized skin eruption similar to measles. The temperature was not above 99 F. at any time. The children were perfectly comfortable. Five of them were asthmatic. On the day following the appearance of the skin eruption, their asthma subsided after having persisted for a month or more. The subsidence of the asthma certainly could not be attributed to fever as there was none to speak of, but I believe it was due to the production of a toxin and that this toxin relieved the children of their asthma by cellular reaction or a sedative action on the autonomic nervous system. To sum up, I wish to say that diathermy may be of benefit in some cases of intractable asthma but that I do not believe that the relief obtained is due to the temperature production per se but to the sedative effects of toxins (from old foci of infection) stirred up, so to speak, by the temperature and having a specific sedative action on the autonomic nervous system or the body cells themselves.

Dr. N. F. Thiberge, New Orleans: While listening to the papers I have tried to catch the different ideas and correlate them all in one harmonious conclusion. A point brought out reminded me of an experience that I had with an allergic patient. When she first presented herself the allergic tests were attended by quite a local reaction. One year after, she gave me the history that she would wake up every morning with an attack of hay fever, and the local site of the previous test would enlarge, inflame, remain swollen as long as the attacks lasted, and then disappear. I directed her every morning when the reaction appeared to massage it but not to massage it too long. Once she tried to massage it more than five minutes and was overcome. She had evidence then of mild anaphylaxis. The point brought out by this is that by massage some antibodies were detached from the cells, and the reaction didn't take place in the tissue but was allowed to take place in the blood stream, where it did not cause any disturbance. I have been trying to correlate that with the diathermy of Dr. Feinberg. It is well known that allergic patients have low blood pressure and that their circulation is sluggish. The antibody being in the cell itself has been well brought out by Rich and Lewis. Might it not be that the effect of the diathermy would be to transfer the reaction by its effect on the circulation: to take the antibodies out of where they are and transfer them into a moving stream, where they can be neutralized by the allergen and produce no reaction whatever? The doctor reports that the eosinophils were not found increased. Might it not be that the paucity of eosinophils in these cases was caused not by the diathermy but by a previous condition of lack of resistance? When the antibody and the allergen meet in the cell itself, they produce the formation of a third substance, and it is only on the production of the third substance that one has the irritation. If this fight is transferred from the cell into the blood current, or into organs that are not shock organs, the reaction takes place without disturbance. In my experience with many thousands of cases during eighteen years, I am more inclined to side with the experience of Dr. Balyeat that one may have, though rather rarely, the reaction to an individual food, the removal of which eliminates the symptoms.

Dr. B. G. Efron, New Orleans: At the last meeting of the Association for the Study of Allergy, I was discussing with some of the men a fever reaction that I was getting with house dust and pollen antigen. Up to Saturday I thought I had something of therapeutic value, because in three of the cases in which fever developed without the ordinary constitutional reaction, the asthma seemed to disappear. But in the last case and in two of the other cases there has been a return of the trouble. I find now that the fever has absolutely nothing to do with the effect on the clinical course of the asthma. The patients that developed fever are no better than those that never got fever. As for the paper of Drs. Rinkel and Balyeat, I wish I knew just what to call "migraine." The symptom complex described as migraine varies with the author. With reference to getting food histories in cases of headache, I have had the same experience that Dr. Piness has had. When I ask a patient whether any food bothers him, as a rule he says: "Sweets and greasy foods usually brother me." That, of course, in allergy is not of great help. My experience with pure food allergy has been similar to that of Dr. Piness. I rarely see a person who is sensitive to foods and foods alone. Usually, here in New Orleans, anyway, inhalant allergy complicates the food cases. I believe that a small number of headaches, so-called migraine, are due to specific foods, but that, in the great majority of cases, if one checks these patients over a long enough period one will find that the relief obtained by the omission of certain foods has been just a transitory affair.

Dr. Clyde Brooks, New Orleans: I have come to the idea (I don't say conclusion) that the fever seen in protein therapy is not essential to improvement in the infectious diseases. In my experience, nonspecific protein is not so efficacious in asthma as it is in infections. In asthma, I find that intravenous injections of small doses of typhoid vaccine are more effective. However, I believe that work such as that done by Dr. Feinberg ought to be continued. As to the relative danger of artificial fever and protein shock, I should prefer the artificial fever. It seems to me that it would not be necessary to press this fever to a high point. Why not use a lower temperature for a longer period?

Dr. I. S. Kahn, San Antonio, Texas: As far as the febrile treatment of asthma is concerned, the fact that similar remissions in the chronic asthmatic state are often seen in pregnancy, which is not accompanied by fever, suggests that the occasional remissions in asthma during febrile infections may be due to the cellular reaction mentioned by Dr. Goltman, and not to the temperature. It is well known that the febrile infections of the respiratory tract actually tend to increase or even initiate the asthmatic symptoms and state. Also, cases of asthma due primarily to any specific antigen may be made decidedly worse by nonspecific agents, such as cold, heat, dust or odors. Hence, the procedure seems to me to be irrational and, at times, dangerous.

Dr. Ray M. Balyeat, Oklahoma City: Dr. Piness asked whether, by history, the food that was causing the patient's migrainous symptoms could ever be detected. In answering that question I should like to ask those who are doing allergic work if it is possible, by history, to detect whether horses would cause a man to have asthma if he came in contact with them, or, by history, if it is possible to detect the fact that orris root brings on hay fever in women who use highly scented cosmetics. Certainly it is true that, in many patients, one can detect by the detailed history at least one or more of the offending foods in the cause of their headaches. Some patients can tell, without any question, the exact food that produces typical migraine, and in referring to migraine here I mean the type of headache that has evidence of cortical involvement. There is no question about that. I should say that there are patients who are sensitive to food and food alone. That is unusual, however, because an individual born with the ability to become sensitive to food ought to become sensitive to inhalants, and they usually do. It is not uncommon in children, for example, to find them sensitive to food and food alone. Later in life, however, they usually develop a sensitivity to inhalants. In practically all the cases that I have reported today, when the foods to which the patients were sensitive were removed from the diet their headaches were relieved, and on putting the foods back into the diet I could reproduce the headache. Dr. Eyermann reported a series of similar cases. Dr. Vaughan has reported similar types of cases, that is, cases in which he could remove the offending food from the diet and relieve the headaches, and could precipitate the headaches by again giving the foods. There are some points in the paper which I barely mentioned, in which I am extremely interested, one being the fact that from the figures it appears in previous work that migraine frequently starts early in life, at least 30 per cent of the patients showing symptoms before 10 years of age. The second point of interest is that, the more classic the picture, the better the results. That is, those who have attacks coming periodically, not regularly, with prodromes and symptoms of cortical involvement, such as scintillating scotomas and sensory and motor symptoms, are the ones who get the best results. Thirdly, epilepsy was uncommon in patients who suffer from headaches due to specific sensitization and headaches in their family tree are uncommon. Somebody reported a series of 110 cases of headache which he spoke of as migraine due to dysfunction of the pituitary. In this series of sixty-five cases that I have reported the average weight of the women was 123 pounds, the average weight of the men was 154 pounds, the average height of the women was 64.26 inches and the average height of the men 67.48 inches. One can see from these figures that the average weight of both the men and women is about the normal for their height. In other words, it appears from our study that probably the dysfunction of the pituitary plays but little part in symptoms that are spoken of as migraine.

Dr. Samuel M. Feinberg, Chicago: One who does allergy work sees over a period of years certain patients who are kept under observation six months, a year, six and seven years, to whom one can give no benefit at all. I mean that a certain number of patients fall in this category, and they have their asthma daily; one tries everything one knows of and then institutes a new method of therapy in which, if any results at all should be obtained, it would be encouraging. All these effects are as the result of one single or one double treatment. By double treatment I mean one treatment two or three days apart and then stopped. If a remission such as this occurs, is one to believe that it is a natural variation in the course of the asthma? If this is merely a psychologic influence, which would happen with any sort of treatment, well and good. If it is the psychologic effect one gets results from, I am for psychology. If that is the psychologic effect of fever treatment, I am going to continue to use it. I can see no reason why this treatment should be more dangerous than foreign proteins and certainly it ought to be less dangerous, because, if for no other reason, one can control the temperature. As to Dr. Peshkin's question, whether I used other treatment during the same time, that might confuse the picture, I used plenty of other treatment prior to the fever therapy. During and subsequent to the fever therapy, I was careful not to use any treatment whatever unless the patient had a relapse. There were three patients who have had from twenty-two to forty-eight weeks relief, and three patients who have had from twelve to twenty-two weeks, something that I couldn't do before with the same class of patients. I think Dr. Thiberge misunderstood me in regard to the eosinophils. I meant that they become lower during the treatment. The eosinophilia returned subsequently, a day or two later. In conclusion, I want to say this work is not advocated as a means of supplanting any type of therapy or any type of procedure in the management of asthmatic patients. It is merely suggested as a possible aid to a certain class of patients whom we are only too glad to wish on one another.

ATYPICAL FACIAL NEURALGIA

DAVID C. WILSON, M.D.
UNIVERSITY, VIRGINIA

The face has become almost synonomous with the personality. Conclusions are reached regarding a person by the regularity or irregularity of his profile. The emotional reaction, the mood and even the character are supposed to correspond to the facial expression. When we say to some one, "Look at me," we mean, "Look at my face." A woman's chief pride is her face. We speak of her face as her fortune. We are told to face our difficulties, and when our failures or shortcomings are exposed, we lose face in the community. To a Chinaman to lose his face is a major calamity. Often it is said that certain people as well as certain things give us a pain in the face. If the ego could be located, it would be placed behind the eyes, but if there is any portion of the body that could represent what we wish other people to think we are and which is the physical manifestation of the ideals of the ego, it is that part of us which meets the constant scrutiny of the world and portrays or conceals our sorrows, our joys and our conflicts. The combination of blood vessels, nerves and muscles that permits this facility of outward expression, as well as of suppression, must be a well organized, finely tuned mechanism. Therefore it is no wonder that shocks to the pride, long suppressed regrets and difficulties recognized but not allowed to reach the surface would cause a functional disturbance of this unit that could become a chronic source of irritation.

Neuralgias of the sensory nerves of the face were described long ago, but Sluder[1] was the first to develop the theory of a neuralgia attributed to the sympathetic nervous system. His syndrome was fairly definite, and he felt that he cured patients so afflicted by injections into the sphenopalatine ganglion. His description of the condition is identical with the description of a symptom complex now given the name of atypical neuralgia of the face, except that he included the migraine types of pain and probably some true tics in his series. In 1920 Cushing[2] wrote of this type of neuralgia, calling it the neuralgia accredited to the sphenopalatine ganglion. He reported the case of a patient, also treated by Sluder, who was not relieved by removal of the sphenopalatine ganglion, and he therefore concluded that the relief sometimes obtained from injections into this ganglion accrued from an accidental paralysis of a nearby maxillary branch of the trigeminal nerve. He also mentioned that occasionally, following operations for major trigeminal neuralgia, there was a residual discomfort in the face similar in many respects to the so-called neuralgia of Sluder.

Frazier[3] studied the symptom complex thoroughly. In 1924, 1925 and 1928, he applied the same atypical neuralgia of the face to the condition, classifying the

neuralgias of the face as follows: first, neuralgia due to infection of the teeth and sinuses, which involves a more or less constant, throbbing pain that subsides with the inflammation; second, postherpetic neuralgias, with a history of rash, constant in character and accompanied by hyperesthesia of the skin; third, neuralgias due to tumors of the gasserian ganglion, which show objective cutaneous changes and hyperesthesia of the cornea; fourth, painful phenomena of the face, which are associated with hemicrania or migraine; fifth, atypical neuralgia, and, sixth, major trigeminal neuralgia.

His description of atypical neuralgia is classic.

> 1. Distribution: (a) Pain is not referred to the peripheral distribution of the nerve, that is, not to the lips, chin, ala of the nose, rather to the cheek, temple, orbit, in front of or behind the ears, and occasionally to the jaws. (b) The pain does not radiate along the course of one or the other nerve tract, it seems unrelated to any anatomic distribution. It will jump across from one zone of the three divisions to another but never to the periphery. (c) The pain extends beyond the trigeminal territory, behind the ear to the submaxillary region, to the shoulder and arm. 2 Character. In the majority of cases the pain is described as drawing or pulling. The thought of pressure disturbance seems dominant, the tissue of the region feels as though under tension; or the pain may be described as burning, an ache sometimes boring or throbbing rather than cutting, stabbing, or tearing It is almost always seated deep in the orbit, deep in the cheek or temple not superficial or terminal. What is particularly noteworthy is that it is constant and not intermittent or paroxysmal though varying in its intensity. It is relieved by opium and is often as bad by night as by day.

Frazier also noted that after trigeminal operation in patients with complete anesthesia of the face there were sometimes the same tension and paresthesias in the paralyzed areas as were found in patients with atypical neuralgias who were not operated on. In nine cases of atypical neuralgia he removed the sphenopalatine ganglion and stripped the sympathetic plexus from the carotid artery, without relief. Five of these patients had had previous section of the trigeminal root, but the combined operation did not relieve the pain. He mentioned one patient who was cured by Christian science, but Frazier was able to find nothing else that would give relief. It seemed characteristic of the condition that any operative procedure made it worse. Glaser [4] analyzed one hundred and forty-three cases of atypical neuralgia. He spoke of their psychogenic nature, but emphasized the lack of success with psychotherapy as well as with other types of therapy. Glaser, Frazier and others who have operated on the cervical sympathetic ganglion with the patient under a local anesthetic mention the pain caused in the face by stimulation of the superior sympathetic ganglion in the neck, but agree that they are unable to relieve atypical neuralgia by sympathectomy. Max Peet [5] believes that he can relieve some patients by separating the ganglion from the vagus and the glossopharyngeal nerve, as well as from the carotid. He is, however, not enthusiastic over his results.

In the meantime the sensory supply of the face has been investigated. Hunt [6] described a zoster zone in the ear and an otalgia that he considered secondary to involvement of the geniculate ganglion. Davis [7] showed that deep sensibility, certainly pain sensation due to pressure, was transmitted by the seventh cranial nerve. Fay [8] demonstrated the overlapping of the cervical nerves into the trigeminal area and described a sensory area in the external ear supplied by the vagus nerve. Doyle,[9] Dandy [10] and Stookey [11] have investigated glossopharyngeal sensation and the neuralgia developing from its involvement, and have described a syndrome in many ways similar to major trigeminal neuralgia but suggestive in its distribution of the atypical type. Stookey states that the attacks of glossopharyngeal neuralgia are paroxysmal, with sudden, severe pain beginning in the throat at the base of the tongue, in the region of the tonsils, and radiating to the area in front of the ear and in some instances down the neck. It is described as sharp, stabbing and stinging. The attacks are frequent, and there is a feeling of dryness in the mouth. Ranson [12] has described unmyelinated fibers in the trigeminal nerve that soon after entering the pons turn caudad into the descending trigeminal root. He believes these carry the sensation of pain. Dandy [13] stated that he can relieve pain in the face by partial posterior section of the trigeminal root close to the pons, without disturbing other sensation. Elsberg [14] suggested that this was due to the section of the unmyelinated fibers described by Ranson. Dandy [15] believes that the abnormal sensations suggestive of atypical neuralgia experienced after section of the fifth nerve are psychogenic. Finally, Davis and Pollock [16] investigated the pain produced on stimulation of the superior cervical sympathetic ganglion in cats. They found that in order to obliterate the sensation, it was necessary to section the posterior cervical roots as well as the trigeminal. They concluded that the stimulation of the sympathetic ganglion produced a disturbance in the deep structures of the face, which, in turn, produced an irritation of sensory nerve endings, thus giving a sensation of pain. Davis [17] explained the appearance of this sensation after trigeminal section as resulting from the irritation of the sensory root of some other cranial nerve.

It may be stated in summary, then, that the sensory supply of the area involved in the atypical neuralgias is from the posterior roots of the cervical nerves, the vagus, the facial, the glossopharyngeal and the trigeminal nerves. There is much evidence, anatomic and experimental, to indicate that there are no afferent fibers supplying the face present in the cervical sympathetic system, but that the sympathetic is in some way involved in the condition under discussion. It also seems that removal of the trigeminal supply does relieve a few patients, while section of fibers from the vagus and glossopharyngeal nerves relieves others; sympathectomy alone does not relieve. The symptom complex of atypical neuralgia, however, is similar and seems to involve the same mechanism as both the migraine-like attacks that accompany or follow hemicrania and the troublesome discomfort occurring in the anesthetic area following trigeminal section, but the neuralgias of the individual cranial nerves, the vagus, the facial, the glossopharyngeal and trigeminal nerves, are separate entities and should not be confused with this condition.

Seven cases of discomfort of the face with the characteristic of atypical neuralgias are herein reported. Three of these patients had had the injection into the sphenopalatine ganglions, four had had teeth removed because of pulp-stones, and all had had much work performed on the nose and on the sinuses.

Case 1 —A woman, aged 45, entered the hospital on March 28, 1932, for treatment after being under observation for several months She gave a history of migraine headaches for many years, which ceased with the production of artificial menopause five years before Soon after that, however, the facial pain developed. It was deep and constant, and extended from the nose across the right malar bone to the ear. There was subjective numbness above the eye, but no pain. At times, however, the pain became severe and paroxysmal, and extended down the neck into the shoulder. The sternomastoid would seem swollen and knotted, she would become nauseated and vomit. The only relief she had obtained during the five years was a six months' period when she was away from home, but since November, 1931, her pain had become severe, and at the time of admission she was having paroxysms three and four times a week The pain seemed almost unbearable, but the emotional reaction to it was even more marked, yet the patient was in good physical condition for one suffering so constantly. Her father and mother had separated soon after her birth; she was raised by her mother, who put her whole life into the child. The girl married at the age of 16. She was active socially for a while, but because it was necessary for her to dominate every situation, she gradually lost her grip on social affairs Five years before I saw her her husband began to drift away, she became suspicious of him, spying on him and watching him closely. Last fall her oldest son, now 25, whom she had tried to possess completely, left home to work in a neighboring town. In November, at the time of her latest exacerbation of symptoms, she became convinced that he was having an affair with a married woman and spent much of her time spying on him and checking his actions. She even mailed her evidence to his employer in order to have her son discharged; she was much upset when this was not carried out. She and her mother do not get along, but her mother stays in the home, caring for the youngest son and running the household

While the patient was in the hospital, she had complete relief from her pain, except on one occasion, when visited by her mother. Since discharge, after the possible psychogenic basis of her difficulty was explained, she has had no pain She stated that she had known for years that the only way for her to get relief was to leave home for a short visit This patient appears to illustrate the migraine-like type of atypical neuralgia. Her mental state could probably be diagnosed as a paranoid condition She has the egotism and the self-righteousness of the true paranoiac. Her facial pain could be interpreted as an exteriorizing process, similar to a paranoid delusion Probably as her delusions become more fixed her pain will disappear permanently

Case 2 —A woman, aged 49 entered Clifton Springs Sanatorium and Clinic in April, 1926 There were an infected right antrum and a retracted tympanic membrane of the right ear, but her complaints were out of all proportion to these symptoms She was extremely agitated and obsessed by a severe grinding sensation in the upper alveolar process, just to the right of the midline, apparently located deep in the bone, between the roof of the mouth and the floor of the nose. She would point to it constantly saying, "It is there, it is there." Pain of an indescribable nature would extend from this region into the ear and down the shoulder. She frequently said, "This pain is so terrible that I can't bear to talk," yet she talked constantly and with seeming facility. She had some buzzing in the ears, and suffered from dizziness and general nervousness. She had been an invalid for five years because of her "agony," although she had had much treatment. The antrum was successfully treated, without improvement in her nervous condition. Psychotherapy was of little avail. She accused her husband of infidelity and her one child of deserting her. She was suspicious and difficult to handle In 1928, however, she returned without the facial pain, although she had many pains elsewhere as well as a slight discharge from the antrum. She confessed that she had separated from her husband soon after her return from her previous admission, because he frankly told her he loved another woman and intended to live with her. The patient is now living on an allowance in the home of her youth She travels extensively, but still complains bitterly that her husband seems to rejoice in the proof of her former suspicions. Up to October, 1931, there had been no return of the pain.

Case 3.—A woman entered the hospital in September, 1931, to have an alcoholic injection into the left maxillary branch of the trigeminal nerve Her neuralgia was of exactly the same type as that described by Sluder, and she had had it for eight years. The pain extended from the ala of the nose across the cheek to the mastoid region, and then down the neck. It was constant and deep, and had periods of varying intensity. A breeze blowing on her face made the pain severe; perspiring increased it. She stated that it caused the utmost agony; yet she was conducting a big business and was a successful aviatrix. Roentgenograms showed many pulp-stones, which she had been advised to have removed. It was then discovered that about eight years previous to entrance, at the time the pain started, she and her husband had worked "the old badger game" on a wealthy and prominent citizen. The remuneration from this had started her business, and, although she apparently went about unconcerned, this pain had developed in the face. The discussion of the episode brought on a severe reaction in the face, and, although she did not return, she wrote that she had remained free from pain until she had one of her teeth removed. She is now under treatment by an allergist, who found her sensitive to several irritants. She is improving under his therapy It is possible that an allergic reaction, as well as the reaction to some psychogenic irritant, might produce this syndrome, but it is doubtful in this case whether dusts or foods could be as powerful an agent as this suppressed memory

Case 4.—A man who entered the hospital first in 1917 and again in 1931 had a domineering but devoted mother, an easy-going father and two younger sisters. As a boy he felt that he could never accomplish a desired objective, because something always held him back. At the age of sixteen he began to have a sense of pressure at the base of the nose, accompanied by a drawing sensation across his face. This caused him to stop school, but he experienced no relief until he entered an embalming school in Cincinnati, at the age of 21. While there he relaxed for the first time, had no pain and did splendid work. On his return home, however, the pressure and tension returned. He had his nose operated on; his mother died, and, finally, he had all his upper teeth removed. For the ten following years the pressure had been continuous. He felt as if wires were drawing his face. On admission he was terribly agitated; his face felt numb, and the bones at the root of the nose were growing into each other; his condition suggested an agitated depression, with marked somatic delusions, yet many of his complaints were those of atypical neuralgia. He went to a private asylum, but left there without relief. Since then, however, he happened to go to Washington, D. C., where he fell in with a very Bohemian group, and soon began to lead a changed life. He returned to his home town in a mildly elated condition and has remained happy ever since. His conduct certainly suggests a hypomanic state, but with the change in behavior came the cessation of pain.

Case 5.—A woman, aged 45, was first seen in October, 1926, and at that time a diagnosis of right-sided sphenopalatine neuralgia was made. The pain was constantly present above her right eye, in her right temple, behind her right ear and in the back of her neck; occasionally it would extend down her neck and into her shoulder. She had spasms of the muscles of the throat, and there was pain when she talked, especially when she gave a hearty laugh. This pain finally caused her to give up her job as teacher and to become a supervisor. Three years ago the pain subsided, but about that time she began to be suspicious of her superiors. Gradually a definite delusion of persecution, well organized and greatly detailed, developed. She is perfectly calm unless this condition is discussed and then her agitation and emotional display are similar to those of agitated depression, which in turn suggests the emotion of atypical neuralgia. In this case again is displayed the egotistical, self-centered personality of the paranoiac patient. The present diagnosis is a paranoid condition, although it is possible that an involutional melancholia will develop later. The most interesting point in this case is the possible substitution of the paranoid delusion for the atypical neuralgia.

Case 6.—A woman, aged 39, was first seen in October, 1930. She first experienced pain in both sides of the neck at 12 years of age. She noted that it returned whenever she was disappointed or emotionally upset. There was no pain in the face, however, until after her husband deserted her, taking all their savings for a trip to New York with another woman. The patient obtained a job and supported her family for a while; then pain developed in the face, and she has been practically an invalid for five years. The pain involves the root of the tongue and the hard palate, and extends across to the right ear and down the neck. There is also some pain on the left side. It is "agony" for her to speak, yet she talks with ease and almost without ceasing. She is suffering "death," but she is the picture of health. Injections have been made into both sphenopalatine ganglions, with relief for only three or four days. Injections were made into the right maxillary division of the trigeminal nerve, but pain returned as promptly as it did after the earlier injections. Injection of procaine into the painful area relieved just as well; this suggests a psychalgia. Her symptoms, her emotional display and her introspection are all typical of the atypical neuralgia. So far nothing has relieved her. Psychotherapy has been of no value.

Case 7.—A woman, aged 36, exhibited symptoms still more suggestive of an obsession. In May, 1931, she began to complain of a secretion with sweet taste which she felt flowing down the left upper incisors. With this she experienced a deep drawing sensation extending into the palate. The most striking thing, however, was the complete upset of her life caused by this slight complaint, as she had given up everything to search for a cure. She was agitated and unable to rest. It was discovered that she had entered the bar in May, 1931, after graduating from a night law school. She had been given a case immediately and had been developing it successfully when this sweet secretion developed, upsetting her to such an extent that she had been forced to give up, not only her case, but her practice of law. Her condition was explained to her as an obsession, but she still went from place to place. Finally, after several weeks in a sanatorium, she was persuaded to accept this conclusion and to try to adjust her life around it. From a superficial point of view it appears that her abnormal sensation was a defense mechanism protecting her from the practice of law. The discomfort showed the distribution, the emotional content and some of the symptoms of a case of atypical neuralgia. She now is entirely free from facial discomfort.

Of the seven patients presented, five had typical atypical neuralgia, one had the migrainous type, and one appeared to have an obsession. All except the last patient had discomfort for many years without relief. All but two now have entire relief, and one is improved. Two patients have definitely paranoid personalities. One of these was relieved from neuralgia when her delusion developed; the other was relieved when removed from an irritating domestic situation. Another patient seems to have manic-depressive psychosis and is now relieved while in a hypomanic state. One patient was relieved by the adjustment of a domestic situation, while another was relieved temporarily by confession and is now experiencing some relief by removal of dust and by eating certain foods. Finally, the one patient who shows no change or improvement is relieved for three or four days by the mere injection of procaine.

From these cases we can conclude that, in addition to the picture described by the neurosurgeons, three other characteristics of atypical neuralgia exist. These are as follows: First, the emotional disturbance and the change in the behavior are out of proportion to the symptoms; second, the personality of these patients is often of a similar type—they are very sensitive, very egotistical and self-centered, in most cases sublimating for an underlying feeling of inferiority, thus making the defense of the ego-superiority so essential; third, their physical well-being seems almost impossible in the presence of such suffering, and suggests that the pain acts like a paranoid delusion, enabling the individual to exteriorize a painful conflict, thus protecting the personality and benefiting body functions. From these cases, also, the conclusion is reached that some cases of atypical neuralgia are psychogenic in origin, some are based on deep conflicts and are part of a developing psychosis, and others are based on a more superficial conflict. We should feel with Davis and Pollock that pain is probably caused by a sympathetic disturbance in the face that is translated into pain by the sensory nerves. In treating such conditions, psychotherapy should come first. Allergy should be tried, but, if surgery is to be attempted, unless the sensory symptoms suggest one particular cranial nerve, there is little likelihood that relief will be obtained unless all cranial nerves are severed. Atypical neuralgias, finally, are thought to be due to a sympathetic disturbance in the face, which may arise from many irritants, but especially from intrapsychic conflicts in which there is danger of loss of self-esteem. The pain leaves when the conflict is solved, and relief can be obtained through psychotherapy.

ABSTRACT OF DISCUSSION

Dr. Edgar F. Fincher, Jr., Atlanta, Ga.: During the past eighteen months it has been my privilege to share offices with Dr. J. D. Thomson, an otolaryngologist, who has interested himself in this particular type of atypical neuralgia: pain in the temporal region, down over the zygoma, behind the ear, and along the trapezius muscle. Using a solution of magnesium sulphate and magnesium borate, in glycerin, he places a small tampon in the auditory canal down against the drum membrane. Over 50 per cent of his results have been noted in three or four hours afterward. Some of these patients have gone as long as five or six months before it was necessary to change the tampon. He has followed these cases for several years without recording his results. I have his permission to say something of his results. Quite a few patients have been treated without any suggestion whatever as to the results or what might be expected following the tampon. No claims have been made as to the psychic or physiologic basis for this treatment. One day a Negro came in with an iritis of traumatic origin, complaining of supra-orbital pain and pain back of his ear and down his shoulder; the pain was so severe that he had had no relief from narcotics. As an experiment, a tampon was placed in his ear and for the first time in two nights he slept comfortably. The results in this case can hardly be attributed to psychotherapy. Undoubtedly some of these cases are of psychogenic origin, but so many persons have this type of atypical pain, always in the same location and always of a similar character, that it must be on an undetermined organic basis. The physiologic or pharmacologic basis for the use of magnesium sulphate is not clear but certainly the results have justified its use in the attempt to relieve the pain in these cases of atypical facial neuralgias.

Dr. Carrol C. Turner, Memphis, Tenn.: Dr. Fincher's remarks substantiate Hunt's ideas of the seventh nerve in subserving sensory function to the deep structures of the face and the external auditory canal and may explain the relief in his cases in that connection. The differentiation of the atypical neuralgias from the major trigeminal neuralgia and facial pain of other origin is extremely difficult. The psychogenic origin of pain must be acknowledged, but on the other hand Alfred Harris has demonstrated that emotional upsets, fear, grief and other emotional strains will just as frequently relieve facial pain as cause it. The extensive hook-up in the facial system, as has been demonstrated by Pollock and Davis in experiments in which they faradized the superior cervical ganglion after bisecting the posterior cervical roots and the proximal trigeminal root, demonstrates the large area subserved by the trifacial system and its associated tracts. It is true that any psychologic disturbance will intensify any symptom, and in a condition in which one has an organic cause for facial pain the psychologic element as a cause of acute exacerbations of that pain must be considered. But when one considers the possibilities of facial pain resulting from pathologic changes in the upper cervical spine, viz., spinal spondylitis, or tumors in the soft tissues of the pterygomaxillary fossa, the psychologic element seems to retreat to some extent. A woman whom I saw recently had been told in another Southern city that she had a chancre of the posterior pharynx and she had a syphilophobia. In spite of negative serologic tests she was convinced that she had had syphilis. In relating her history to me in the office she manifested facial pain with atypical paroxysms. Further investigation showed no evidence whatever of syphilis. She was referred to an otologist, who found a tumor in the pterygomaxillary fossa, and after removal of this tumor the patient had an uneventful recovery and there has been no recurrence of pain since.

Dr. David C. Wilson, University, Va.: I never have seen one of these patients relieved by injection of the sphenopalatine ganglion. A study of the literature showed that certainly there were very few instances of relief by any method of therapy and that was one of the points I wanted to make here, as here there were five patients that had been relieved for quite a little period of time, a most unusual circumstance. Dr. Fincher's method of relief, of course, I do not know anything about. Dr. Davis's work on facial nerves is interesting, and when one sees these cases one must think that section of the seventh nerve might give relief. Another point from the psychologic standpoint would be that the injury to the ego is certainly expressed in the face, and it seems to me from a psychologic standpoint that there is every reason why one should expect such injuries to the personality, to the ideals or to the ambitions of the person to be expressed in some disorder of the face. That is, when there is injury to the ego, indeed, when persons seem to be failing in their ambitions of life, there is disturbance in this mechanism which expresses or suppresses the emotions, which is interpreted as pain.

Splenic Anemia.—With the exception of aplastic anemia, all the chronic diseases of the blood-forming organs tend to produce enlargement of the spleen, whether they involve initially the red cells, white cells or platelets. On this account the coexistence of anemia, leukopenia and splenomegaly never justifies an immediate diagnosis of splenic anemia, but for lack of further investigation and observation I have several times seen aleukemic leukemia, essential thrombopenia, and simple achlorhydric and allied anemias masquerade under this too comprehensive diagnosis. Splenic anemia is in reality a rare disease. Enlargement of the spleen and anemia are more commonly the result of an independent disease of the blood-forming organs than of splenic anemia. It is now becoming accepted that splenic anemia is always the result of high pressure in the portal circulation, and that in the great majority of cases this is due to primary disease of the liver, though the morbid change in the liver may be visible under the microscope only. The anemia is the result of the raised portal pressure, as has often been shown in experimental animals. Identical anemia occurs in Laënnec's cirrhosis of the ver. It is unwise to diagnose splenic anemia in the absence signs of raised portal pressure or of liver damage without most careful circumspection.—Witts, L. J.: The Pathology Treatment of Anemia, *Lancet* **1**:495 (March 5) 1932.

EFFECT OF DIGITALIS ON ARRHYTHMIAS OTHER THAN FLUTTER AND FIBRILLATION OF AURICLES

CHARLES W. BARRIER, M.D.
FORT WORTH, TEXAS

AURICULAR TACHYCARDIA

In 1926 Otto and Gold[1] stated that the results obtained in treating patients with paroxysmal tachycardia with digitalis were extremely variable. White[2] remarked that digitalis, even in adequate doses by vein, is usually ineffective during an attack. Levine and Blotner,[3] however, by employing full doses, were more successful. Wilson and Wishart,[4] in 1930, reported the first two cases in which digitalis given intravenously produced marked slowing of the heart rate followed by cessation of the paroxysms. Barrier[5] reported cessation of the paroxysms in six of eight cases.

I do not make this report as a plea for the use of digitalis in paroxysmal tachycardia, but merely to show its effect on the arrhythmia, in the hope that some light may be shed on the mechanism of paroxysmal tachycardia and on the mode of action of digitalis. The patients on whom similar studies have been made and reported in the literature have been under observation for only short periods, and the paroxysms usually terminated spontaneously after brief attacks. My studies on auricular tachycardia are based on two patients whom I have observed for over four years and in whom the paroxysms were not observed to terminate spontaneously.

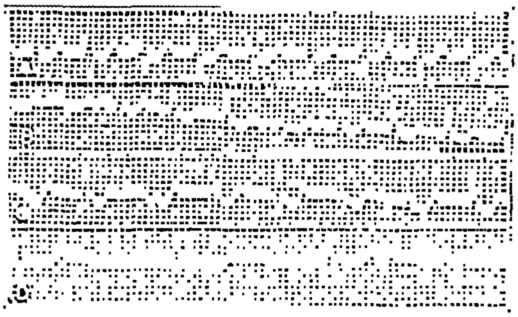

Fig. 1 (case 1).—Nodal tachycardia: reduction in rate and return of sinus rhythm after digitalis: *A*, rate 180 at 11: 55 p. m.; 5 cc. of digalen given at 12 a. m. *B*, rate 165 at 12: 12 a. m.; 5 cc. of digalen given at 12: 24 a. m. *C*, rate 145 at 12: 41 a. m. *D*, rate 55 at 1 a. m.

Case 1.—A woman, aged 21, who had no lesion of the heart, said that her heart rate had been above 160 for the three years previous to seeing me in 1928, at which time she had a supraventricular tachycardia, the rate being 160. Since then sinus mechanism had followed the administration of digitalis and quinidine on numerous occasions, and attacks had been warded off for long intervals by either drug. No physical stimulation of the vagus could restore sinus rhythm. The rate at the inception of a paroxysm was well above 200, but after several hours it slowed to between 160 and 180 spontaneously.

the back of her neck; occasionally it would extend down her neck and into her shoulder. She had spasms of the muscles of the throat, and there was pain when she talked, especially when she gave a hearty laugh. This pain finally caused her to give up her job as teacher and to become a supervisor. Three years ago the pain subsided, but about that time she began to be suspicious of her superiors. Gradually a definite delusion of persecution, well organized and greatly detailed, developed. She is perfectly calm unless this condition is discussed and then her agitation and emotional display are similar to those of agitated depression, which in turn suggests the emotion of atypical neuralgia. In this case again is displayed the egotistical, self-centered personality of the paranoiac patient. The present diagnosis is a paranoid condition, although it is possible that an involutional melancholia will develop later. The most interesting point in this case is the possible substitution of the paranoid delusion for the atypical neuralgia.

Case 6.—A woman, aged 39, was first seen in October, 1930. She first experienced pain in both sides of the neck at 12 years of age. She noted that it returned whenever she was disappointed or emotionally upset. There was no pain in the face, however, until after her husband deserted her, taking all their savings for a trip to New York with another woman. The patient obtained a job and supported her family for a while; then pain developed in the face, and she has been practically an invalid for five years. The pain involves the root of the tongue and the hard palate, and extends across to the right ear and down the neck. There is also some pain on the left side. It is "agony" for her to speak, yet she talks with ease and almost without ceasing. She is suffering "death," but she is the picture of health. Injections have been made into both sphenopalatine ganglions, with relief for only three or four days. Injections were made into the right maxillary division of the trigeminal nerve, but pain returned as promptly as it did after the earlier injections. Injection of procaine into the painful area relieved just as well; this suggests a psychalgia. Her symptoms, her emotional display and her introspection are all typical of the atypical neuralgia. So far nothing has relieved her. Psychotherapy has been of no value.

Case 7.—A woman, aged 36, exhibited symptoms still more suggestive of an obsession. In May, 1931, she began to complain of a secretion with sweet taste which she felt flowing down the left upper incisors. With this she experienced a deep drawing sensation extending into the palate. The most striking thing, however, was the complete upset of her life caused by this slight complaint, as she had given up everything to search for a cure. She was agitated and unable to rest. It was discovered that she had entered the bar in May, 1931, after graduating from a night law school. She had been given a case immediately and had been developing it successfully when this sweet secretion developed, upsetting her to such an extent that she had been forced to give up, not only her case, but her practice of law. Her condition was explained to her as an obsession, but she still went from place to place. Finally, after several weeks in a sanatorium, she was persuaded to accept this conclusion and to try to adjust her life around it. From a superficial point of view it appears that her abnormal sensation was a defense mechanism protecting her from the practice of law. The discomfort showed the distribution, the emotional content and some of the symptoms of a case of atypical neuralgia. She now is entirely free from facial discomfort.

Of the seven patients presented, five had typical atypical neuralgia, one had the migrainous type, and one appeared to have an obsession. All except the last patient had discomfort for many years without relief. All but two now have entire relief, and one is improved. Two patients have definitely paranoid personalities. One of these was relieved from neuralgia when her delusion developed; the other was relieved when removed from an irritating domestic situation. Another patient seems to have manic-depressive psychosis and is now relieved while in a hypomanic state. One patient was relieved by the adjustment of a domestic situation, while another was relieved temporarily by confession and is now experiencing some relief by removal of dust and by eating certain foods. Finally, the one patient who shows no change or improvement is relieved for three or four days by the mere injection of procaine.

From these cases we can conclude that, in addition to the picture described by the neurosurgeons, three other characteristics of atypical neuralgia exist. These are as follows: First, the emotional disturbance and the change in the behavior are out of proportion to the symptoms; second, the personality of these patients is often of a similar type—they are very sensitive, very egotistical and self-centered, in most cases sublimating for an underlying feeling of inferiority, thus making the defense of the ego-superiority so essential; third, their physical well-being seems almost impossible in the presence of such suffering, and suggests that the pain acts like a paranoid delusion, enabling the individual to exteriorize a painful conflict, thus protecting the personality and benefiting body functions. EFFECT OF DIGITALIS ON ARRHYTHMIAS OTHER THAN FLUTTER AND FIBRILLATION OF AURICLES

CHARLES W. BARRIER, M.D.
FORT WORTH, TEXAS

AURICULAR TACHYCARDIA

In 1926 Otto and Gold[1] stated that the results obtained in treating patients with paroxysmal tachycardia with digitalis were extremely variable. White[2] remarked that digitalis, even in adequate doses by vein, is usually ineffective during an attack. Levine and Blotner,[3] however, by employing full doses, were more successful. Wilson and Wishart,[4] in 1930, reported the first two cases in which digitalis given intravenously produced marked slowing of the heart rate followed by cessation of the paroxysms. Barrier[5] reported cessation of the paroxysms in six of eight cases.

I do not make this report as a plea for the use of digitalis in paroxysmal tachycardia, but merely to show its effect on the arrhythmia, in the hope that some light may be shed on the mechanism of paroxysmal tachycardia and on the mode of action of digitalis. The patients on whom similar studies have been made and reported in the literature have been under observation for only short periods, and the paroxysms usually terminated spontaneously after brief attacks. My studies on auricular tachycardia are based on two patients whom I have observed for over four years and in whom the paroxysms were not observed to terminate spontaneously.

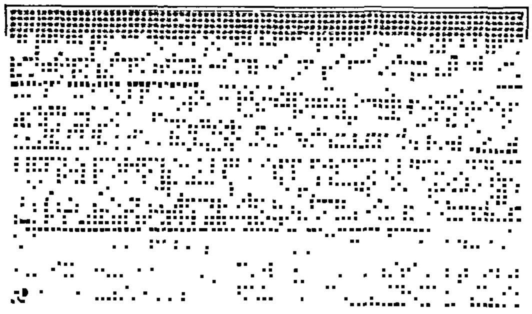

Fig 1 (case 1)—Nodal tachycardia: reduction in rate and return of sinus rhythm after digitalis *A*, rate 180 at 11 55 p m, 5 cc of digalen given at 12 a m *B*, rate 165 at 12 12 a m, 5 cc of digalen given at 12.24 a m *C*, rate 145 at 12.41 a. m *D*, rate 55 at 1 a m.

Case 1.—A woman, aged 21, who had no lesion of the heart, said that her heart rate had been above 160 for the three years previous to seeing me in 1928, at which time she had a supraventricular tachycardia, the rate being 160. Since then sinus mechanism had followed the administration of digitalis and quinidine on numerous occasions, and attacks had been warded off for long intervals by either drug. No physical stimulation of the vagus could restore sinus rhythm The rate at the inception of a paroxysm was well above 200, but after several hours it slowed to between 160 and 180 spontaneously.

No digitalis was given for two months and no quinidine for ten days, at the end of which the patient entered the hospital twelve hours after the onset of an attack with a rate of 180. Twelve minutes after 5 cc. of digalen was given by vein the rate had dropped to 165, and at the end of forty-one minutes it was 145, another 5 cc. of digalen having been given in the meantime. At the end of an hour the rate suddenly dropped to 55, sinus mechanism being present. The slowing of the paroxysmal rate was due to an increased length of diastole. While quinidine also slowed the rate and then produced sinus mechanism in this patient, the order of events was somewhat reversed. The slowing was principally in the R-T interval. Sinus mechanism resulted much earlier, the rate at first being almost as fast as the paroxysmal rate. A gradual reduction of the sinus rate then followed.

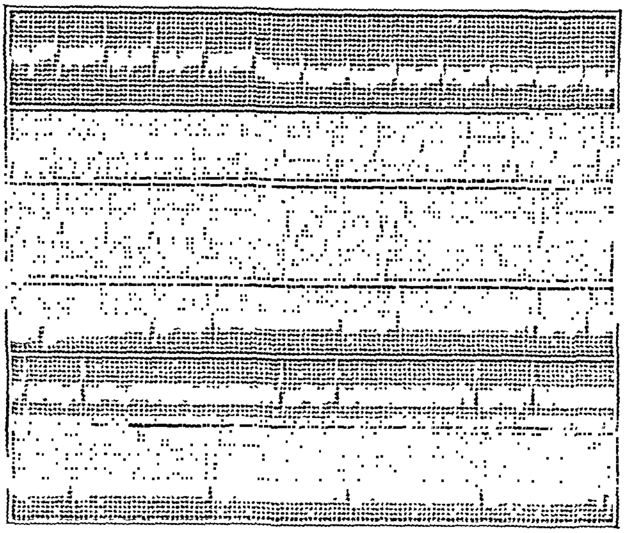

Fig. 2.—Auricular tachycardia. Vagal stimulation (deep breathing).

Case 2.—A man, aged 21, had had tachycardia for six years previous to the present experiments, except when taking digitalis. Sinus rhythm and long periods of freedom from paroxysms had followed massive doses of digitalis on numerous occasions. At the onset of a paroxysm the rate was around 190 or 200, but after a week or so it dropped to 120, but rose rapidly after exercise or excitement.

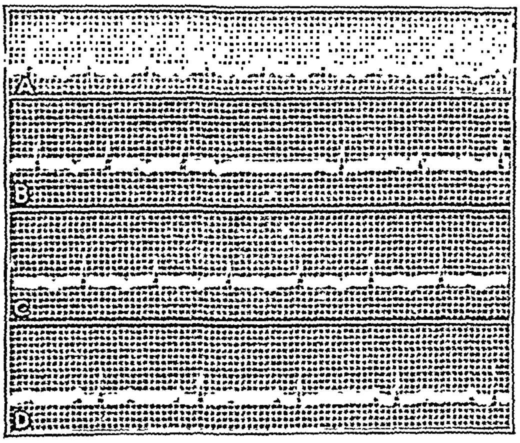

Fig. 3 (case 2).—Slowing of rate and return of sinus rhythm after digitalis: *A*, rate 155 before digitalis. Ten cubic centimeters of digifoline given at 8: 06. *B*, vagus stimulation at 8: 19; 5 cc. of digifoline given at 8: 20. *C*, rate 140 at 8: 26; increased P-R time. *D*, rate 95 at 8: 36; sinus mechanism.

The patient was peculiarly susceptible to vagal stimulation. Figure 2 is a continuous tracing, showing the interruption of a paroxysm by holding the breath after a forced inspiration. In it are noted changes of the P-R interval: auricular-ventricular block followed by sinus mechanism and sino-auricular block with ventricular escape and a period of sinus bradycardia. Pressure on the eyeball increased the P-R time, slowed the rate of the paroxysm and occasionally produced a short run of two to one auricular-ventricular block, which was followed by a sinus block and the inception of sinus mechanism. After all forms of mechanical stimulation of the vagus, sinus mechanism was of short duration.

Quinidine never, even in toxic doses, produced sinus mechanism, although when given by vein it slowed the rate. The P-R time was unchanged. After the administration of quinidine, vagal stimulation further slowed the rate of the paroxysm, but did not produce sinus mechanism.

After discontinuing the use of digitalis for three weeks, the patient entered the hospital with an attack of auricular tachycardia. An intravenous injection of digitalis lengthened the P-R interval, slowed the rate and, in thirty minutes, produced sinus mechanism.

A month later the patient entered the hospital during an attack, with a rate of 145. Atropine and digitalis were given together. Early there were short runs of sinus mechanism at an increased rate. Otto and Gold[1] reported a similar experience. Finally, the auricular tachycardia persisted, digitalis failing to interrupt it as when the vagus was not paralyzed by atropine; neither was the P-R interval lengthened.

In the first case digitalis, possibly through its direct action on the heart muscle in slowing the rate of conduction and in introducing intra-auricular block by an increased refractory period, slowed the rate and abolished the paroxysm, respectively. This is contrary to the usual action of digitalis in cases of circus movement, such as flutter of the auricles, in which its vagal action overrules its direct effect, thus perpetuating the circus movement and increasing the rate by decreasing the refractory period and speeding up conduction.

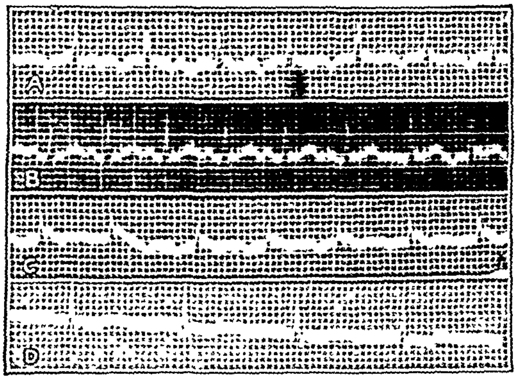

Fig. 4 (case 2).—Auricular tachycardia showing lack of response to digitalis after atropine: *A*, rate 145 at 8: 10; 1/15 grain (0.004 Gm.) of atropine and 10 cc. of digifoline given between 8: 23 and 9. *B*, rate 158 at 9: 10; 5 cc. of digifoline given at 9: 27. *C*, rate 145 at 10; auricular tachycardia. *D*, sinus mechanism next morning.

In the second case the action of digitalis was probably through the vagus by depressing conduction and diminishing stimulus formation. While the exact way in which increased vagus tone abolished the paroxysm is not known, one can be fairly certain that the effect of digitalis was through the vagus; first, because the heart under digitalis behaved almost identically as under physical vagus stimulation, and second, because digitalis failed to act when the vagus was paralyzed by atropine.

In the first case digitalis and quinidine probably acted in the same way qualitatively, but not quantitatively. Quinidine probably effected an earlier and more profound increase of the refractory period. Quinidine in the second case acted directly on the heart muscle, but failed to abolish the paroxysm as it often does in flutter by increasing the length of the circus out of proportion to the refractory period increase.

EXTRASYSTOLIC ARRHYTHMIA

The innocent nature and extreme frequency of extrasystoles are too well known to require comment. Yet, there are a few patients who consult the cardiologist primarily because of this arrhythmia who need treatment. Schwarts reported cases of heart disease in which auricular extrasystoles were followed by fibrillation with a rapid ventricular rate and heart failure. Digitalis abolished the extrasystole and prevented fibrillation.

Digitalis in large doses will abolish the arrhythmia in a larger number of cases than the literature would indicate, and this effect is of interest to the student of digitalis and cardiac arrhythmias, especially when the rôle of digitalis in the causation of extrasystoles is so well known.

Case 3.—A young woman with a mild degree of mitral stenosis and a slightly enlarged heart complained of early palpitation and undue dyspnea on moderate exertion such as dancing, a pastime she did not wish to give up. An occasional extrasystole was noted after rest; after exercise, the radial pulse was counted at 45, but a bigeminy was noted at the heart. Eight cubic centimeters of digalen abolished all extrasystoles while at rest; after exercise, they were still, but only occasionally, noted. After 4 cc. more, extrasystoles could not be induced by exercise. The patient could then dance without palpitation or dyspnea.

Case 4.—A man, aged 54, complained of severe substernal pain on effort of three months' duration. Two days later he had a typical attack of coronary occlusion and was kept in bed for three months. Six weeks later he complained of a spell of cardiac irregularity, especially for the first few hours after arising, which made him quite miserable. He was also dyspneic on rather moderate exertion. A junctional extrasystolic arrhythmia was found. As I knew that digitalis might excite dangerous ventricular rhythms after coronary occlusion, I hesitated several days. Quinidine was not given because of the dyspnea. As the symptoms grew more annoying, it was decided to digitalize slowly, but completely. In several days the patient was free from arrhythmia, except for an occasional extrasystole, and had no dyspnea. He still takes 2 grains (0.13 Gm.) of digitalis daily and has no cardiac symptoms.

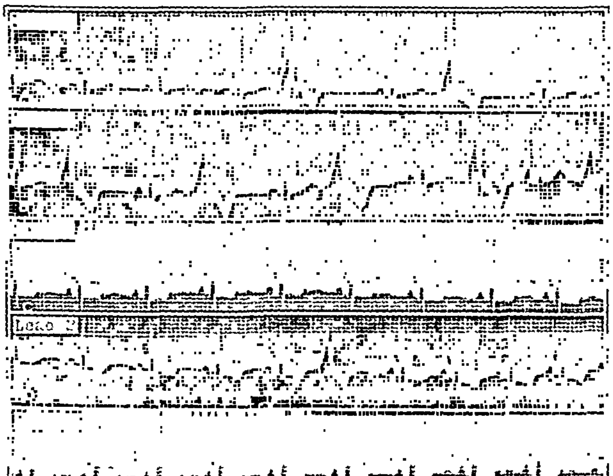

Fig. 5 (case 3).—Numerous extrasystoles, increased by exercise; abolished by full doses of digitalis. *A*, after rest. *B*, after exercise. *C*, 8 cc. of digalen given; after rest. *D*, after exercise. *E*, 12 cc. of digalen given; after exercise.

Case 5.—A young man, without a cardiac lesion, consulted me because of extrasystoles, which proved to be auricular. Permission was obtained to test the effect of digitalis and of quinidine. Each drug in full doses abolished the arrhythmia.

Case 6.—A woman, aged 60, who was first seen five years ago, complained of palpitation, a moderate degree being present at all times; several times a day there were severe spells with giddiness so marked that she had to lie down. The electrocardiogram revealed a sinus bradycardia with frequent extrasystoles. She undoubtedly had short spells of ventricular tachycardia. As these extrasystoles were not transmitted to the pulse, the rate was at times as low as from 25 to 30. Atropine and quinidine controlled the condition for a while, but as their effects were unpleasant, digitalis was given. The patient took from 3 to 5 grains (0.19 to 0.32 Gm.) a day over a period of two years, with the result that the sinus rate was increased and the extrasystoles were abolished. An occasional spell of palpitation followed gaseous distention.

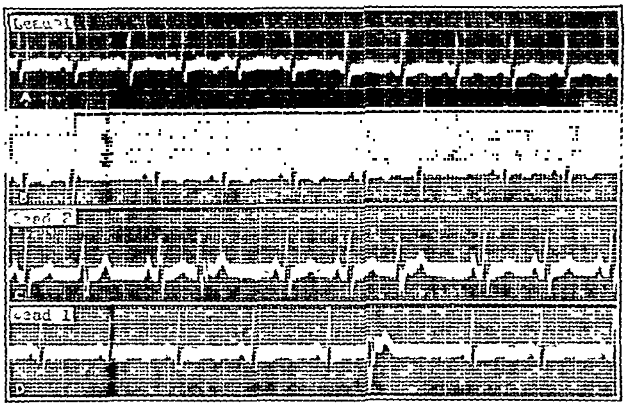

Fig. 6 (case 4).—Coronary occlusion with moderate heart failure and numerous extrasystoles; almost completely abolished by digitalis: *A*, Oct. 2, 1931, before coronary occlusion. *B*, March 1, 1932, four and one-half months after coronary occlusion. *C*, numerous extrasystoles. *D*, March 8, occasional extrasystole after digitalis by mouth.

The mechanism of this arrhythmia is probably a circus movement. The exact way in which digitalis abolishes the circus is no better understood than is its effect on paroxysmal tachycardia.

SUMMARY

In two cases of supraventricular tachycardia, digitalis was given by vein and was followed by slowing of the rate of the paroxysm and the restoration of sinus rhythm.

In one case the effect was supposed to be due to direct action of digitalis on the heart muscle. In the other case the effect was thought to be due to increased vagal tone as the heart under digitalis behaved as when the vagus was mechanically stimulated and because digitalis failed to abolish the paroxysm after the vagus was paralyzed by atropine.

In extrasystolic arrhythmia the use of digitalis is occasionally of benefit in relieving both the disturbing rhythm and the symptoms of heart failure. It will abolish extrasystoles more frequently than the literature would indicate.

Cases are reported in which all three types of extrasystoles were abolished.

Digitalis is probably effective through its action on certain factors involved in circus movement.

ABSTRACT OF DISCUSSION

Dr. Wallace M. Yater, Washington, D. C.: Dr. Barrier's paper is valuable because of the long period of time over which he was able to follow his patients very carefully. It is rather confusing, however, in view of the increasing number of reports of cases of paroxysmal tachycardia which are definitely produced by the use of digitalis. The effect of digitalis in producing or at least augmenting the appearance of ectopic beats is notorious. The known effects of digitalis, of course, are two; namely, the indirect effect on the heart due to vagus stimulation and the direct effect on the heart muscle. The predominance of the vagus effect in slowing the rate of normal stimulus production would theoretically tend to continuation of the tachycardia in cases of paroxysmal tachycardia, since there would be reduced opposition to the activity of the focus that was carrying on. On the other hand, in the case of extrasystoles, the direct effect of digitalis on the muscle, increasing its tone and irritability, would make conditions more favorable to the production of extrasystoles. It may be in such cases as Dr. Barrier reports it is the opposite effects to these which are responsible for changing the rhythms and allowing normal rhythm to be reestablished. At any rate, it is such reports as these, carefully studied and carefully followed, that indicate that more intensive work is necessary on the fundamental nature of the action of digitalis.

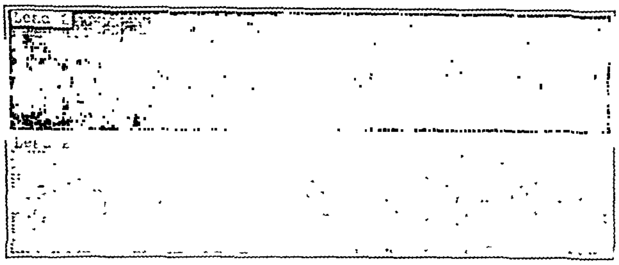

Fig. 7 (case 5).—Frequent auricular extrasystoles (bigeminy); abolished by both digitalis and quinidine.

Dr. Louis F. Bishop, Jr., New York: I should just like to call attention to one point in Dr. Barrier's paper which interested me. This was the fact that in paroxysmal tachycardia of the *supraventricular* type digitalis was effective. I should like to ask whether he has tried it in other types of tachycardia with any results. Digitalis given in small doses very often, I have found, abolishes extrasystoles. The mechanism of its action is somewhat uncertain. I think Dr. Barrier has also shown that it is often a valuable drug in abolishing certain extrasystolic arrhythmias and probably should be tried more often than it is.

Dr. W. E. Garrey, Nashville, Tenn.: I want to call attention to the fact that physicians do not always keep in mind certain definite mechanisms in connection with the production of extrasystoles and also fail to recognize certain well established physiologic facts with reference to the innervation of the ventricle and the conducting system by the vagus. The fact should be recognized that there are many and various mechanisms for the production of extrasystoles. Some of these, such as those that are effective in the production of paroxysmal tachycardia, may well be circus movements which are high up in the conducting system of the ventricle. These are readily affected by vagus action. However, the vagus does not affect the lower portion of the ventricular musculature but only the conducting system. For that reason one gets the combination of paradoxical effects by the administration of digitalis, namely, that one breaks the circus movements if one has the ectopic effects high in the conducting system, but may fail entirely and actually increase the excitability of certain foci in the ventricle through the action of digitalis on the augmentor or accelerator centers, as has been brought out so clearly in the work of Dr. J. T. Halsey. I think probably it may be well to recognize these apparent so-called reverse or paradoxical effects, depending entirely on the anatomic distribution of the vagus and augmentor nerves in the ventricle.

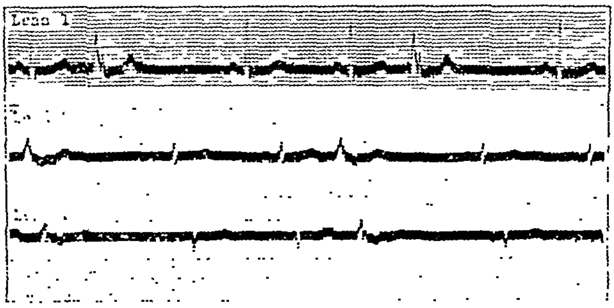

Fig. 8 (case 6).—Sinus bradycardia with frequent extrasystoles; abolished by large doses of digitalis by mouth.

Dr. Charles W. Barrier, Fort Worth, Texas: I feel like making a slight apology to the section for presenting a subject about which many cardiologists believe there is no need of drugs. They feel that these are minor cardiac arrhythmias, alarming to the patients but of little importance clinically. Dr. Bishop asked about the effect of digitalis in ventricular tachycardia. I have not used digitalis in pure ventricular tachycardias, believing that in these cases it is dangerous. In the only cases that I have seen, the patients have been relieved with quinidine or have died. I have, however, noted cases of nodal tachycardia in which the T wave followed the QRS complex that responded well to digitalis. Dr. Garrey's remarks are very important, but they do not exactly explain why these auricular tachycardias which are probably due to circus movement respond so well to digitalis, while other circus movements that are almost the same, such as flutter, do not respond to digitalis but are really aggravated by the drug.

SCLEREDEMA ADULTORUM (BUSCHKE)

NORMAN N. EPSTEIN, M.D.
SAN FRANCISCO

The recent observation of two patients who presented the clinical picture of scleredema adultorum of Buschke is the subject of this report. Although well recognized in Germany and by some French writers, this disease has received little attention elsewhere.

REVIEW OF THE LITERATURE

Buschke,[1] in 1902, was the first to distinguish scleredema adultorum as a clinical entity, and he reported a classic case in that year. He adopted the name "scleredema adultorum" because he thought it resembled sclerema of infants. Since that time, forty additional cases have been reported. Of the entire number, thirty-nine were found in the German literature and two in the French.

Buschke,[2] Hoffmann,[3] Nobl,[4] Sellei,[5] Rummert,[6] Mayr[7] and Freund[8] have made important contributions to the subject. The following table gives all of the reported cases that could be found, presented in the order of their publication. Two cases reported by Pinkus have been omitted from the table as they differ in certain important respects from scleredema adultorum. The first is an instance of diffuse scleroderma, while the second was finally diagnosed as Dercum's disease or adiposa dolorosa.

REPORT OF CASES

Case 1.—*History.*—C. C., an Italian woman, aged 31, married, first entered the University of California Hospital on May 6, 1916, at the age of 15. She complained of stiffness of the skin of the arms, neck and face.

The family history was unimportant.

From the Division of Dermatology, University of California Medical School, and the Department of Dermatology, Mount Zion Hospital.

Read before the Section on Dermatology and Syphilology at the Eighty-Third Annual Session of the American Medical Association, New Orleans, May 11, 1932.

The patient had resided in San Francisco until the age of 15 years. She had had measles in infancy. Catamenia began at the age of 13, and had always been normal.

Four weeks before entry, having been perfectly well previously, the patient began to have daily attacks of fever accompanied by chilly sensations. The fever developed about 4 p. m. each day. Two weeks before admission the fever ceased suddenly, and about this time an erythematous eruption appeared over the extensor surfaces of the forearms and knees and over the neck and face. Following the onset of the eruption the patient's skin over the forearms became firm and stiff. The sides of the neck and the face soon became involved. She complained of severe itching over these areas.

Examination.—The natural lines of the face had been obliterated, giving a masklike expression. The hair was thin, with moderate seborrhea. The reflexes and sensation were normal. The lids were swollen and stiff. The tonsils were large. The skin of the neck, shoulders, arms, forearms and face was firm and smooth. There were no changes except that where the erythematous eruption had been the skin was darker than normal. The induration disappeared over the abdomen and was present to a less extent over the thighs and legs. The hands and feet were unaffected. The skin did not pit on pressure.

Laboratory Work.—A blood count and urinalysis gave normal results. The tuberculin test gave negative results. The Wassermann reaction was negative.

Course.—The patient received thyroid extract, 0.3 Gm., three times a day. The erythematous eruption disappeared in a few days. On July 7, tonsillectomy was performed. The condition of the skin had practically cleared in five months.

The patient reentered the University of California Hospital on Jan. 6, 1929.

Interval History.—At the second entry the patient had been married for seven years. She had one child who was living and well. Her husband was living and well. She had had rheumatic fever four years and one year previously. She had not had a sore throat.

At the time of admission she complained of stiffness of the skin of the whole body.

The patient was quite well until two weeks before admission, when she was taken down with the "flu" (pains and aches in the back, fever and chills). She was confined to bed four days and then, as she felt perfectly well, was allowed to be up and around. Five days later reddish annular blotches appeared on the flexor surface of the forearms and arms. These disappeared one day later. Following this the patient noticed an increasing stiffness and tightness of the skin, particularly on the upper extremities, face and neck.

Examination.—The observations were the same as on the previous entry, except for the heart, which showed a presystolic and a systolic murmur all over the precordium. The tonsils had been removed.

The patient's skin showed a more extensive involvement than on the previous entry. The expression was masklike. The mouth could be opened only with difficulty. The skin of the neck, shoulders, back, face, chest and abdomen was hard and stiff and could not be picked up in folds. The induration was present over the thighs and legs, but to a lesser degree. This change in induration was not sharp, but shaded off imperceptibly. The hands were somewhat stiffened, but the fingers and feet were unaffected. No abnormal pigmentation was present.

Laboratory Work.—Examination of the blood showed: hemoglobin, 78 per cent; red cells, 4,684,000; white cells, 10,360, with a normal differential count. The urine was normal. The Wassermann reaction was negative. Examination of the stool gave negative results. The basal metabolic rate was 18.6 per cent plus. The visual field was normal. A dextrose tolerance test showed: fasting blood sugar, 0.83 mg.; first specimen, 0.134 mg.; second specimen, 0.146 mg.; third specimen, 0.116 mg.

A biopsy specimen was taken from the right forearm. The urine was negative for arsenic.

Course.—The patient has been under observation in the outpatient department up to the present time. The induration of the skin gradually subsided; the masklike expression slowly changed to normal, and the patient regained the ability to open her mouth to its full extent. Except for a slight residual stiffness over the shoulders, the skin is now entirely normal. No atrophy is present.

CASE 2.—*History.*—R. B., a man, aged 43, a printer, was admitted to Mount Zion Hospital on Sept. 23, 1929, with the complaint that the skin felt tight over the neck, face, chest, back and abdomen.

The family history was unessential.

The patient had measles and smallpox in childhood. He had not had rheumatic fever. He had pneumonia in 1910. The patient said that he had not had a venereal disease. He had fractured his ankle and two ribs in 1913, with an uneventful recovery. No operation had been performed.

The patient's wife had had one miscarriage; one child had died during delivery.

Six weeks prior to admission the patient had had a tooth pulled. His jaw was swollen and painful for a week, and chips of bone discharged from the wound. The tonsils became swollen and reddened; pus drained from the left. Ten days before admission the patient began to have a sensation of tightness over his neck, which progressed over the back, chest and face.

At the age of 16 the patient had first noticed a stiffness of the skin of the back, which extended around in front of the neck. He could not remember any definite preceding febrile episode, but had had several attacks of grip about that time. The skin remained quite rigid for a few months, and then subsided.

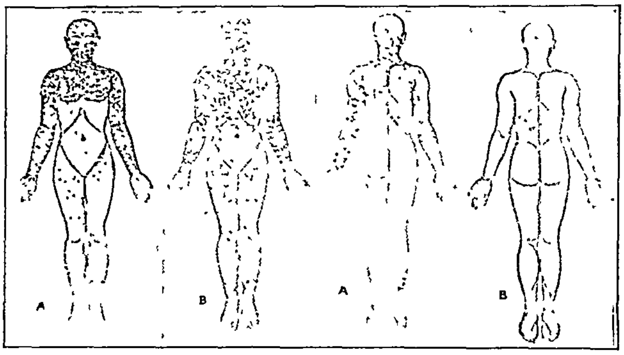

Fig. 1.—Diagram showing distribution of induration. *A*, case 1. *B*, case 2.

Examination.—This showed a tightness of the skin of the face, neck, chest and back. The skin was less firm over the buttocks and lower limbs.

The teeth were carious. The tonsils were greatly hypertrophied and reddened; there was a discharge of pus from the left tonsil. There was no adenopathy. The chest, heart and abdomen were normal except for the skin.

Laboratory Work.—On September 19, examination of the blood showed: hemoglobin, 96 per cent; red cells, 5,040,000; white cells, 6,400; polymorphonuclears, 52 per cent; lymphocytes, 45 per cent, and transitionals, 3 per cent. The Wassermann reaction was negative. The coagulation time was four minutes; the bleeding time, two minutes. The urine was normal. A biopsy specimen was taken from the right shoulder. The urine was negative for lead and arsenic. A phenolsulphonphthalein test showed: 45 per cent, first specimen; 22 per cent, second specimen; total, 67 per cent. The basal metabolic rate was 3 per cent plus.

X-ray pictures of the hands were negative for circulatory disturbances.

Course.—While the patient was in the hospital a tonsillectomy was performed. He was discharged on October 10. He has been observed in the outpatient department at frequent intervals. The rigidity of the skin slowly subsided, so that when last seen only a slight amount of residual induration remained over the wall of the chest. The patient complained of a tightness about the anus, and his lips were stiff at times. The skin at no time pitted on pressure There was no resultant atrophy or increased pigmentation Although not entirely well, the patient is greatly improved

CLINICAL MANIFESTATIONS

Scleredema adultorum is characterized by progressive induration and swelling of the deeper portions of the skin and subcutaneous tissues As a result, the skin becomes hard and rigid and cannot be lifted up into folds The normal markings are obliterated, giving a smooth, shiny appearance On palpation the skin is of boardlike consistency and does not pit on pressure. Except for this, there are no other changes in the epidermis Sensation is unchanged, sweating may be normal or slightly decreased, there is no loss of hair, there are no changes in pigmentation, and there are no signs of inflammation When the process subsides, the skin returns completely to normal Atrophy is never seen.

The induration usually begins at the nape of the neck and spreads quite rapidly to the front of the neck and the face It then progresses downward over the back and chest, becoming almost imperceptibly less marked over the lower portions of the trunk The pelvic girdle and lower extremities are less often affected and to a lesser degree than the shoulders, neck and face The hands and feet are never involved, although induration of the hypothenar eminences sometimes occurs A transient erythematous eruption occasionally precedes the development of the induration

Reported Cases of Scleredema Adultorum

Case	Author	Date of Report	Sex	Age	History of Preceding Infection	Distribution and Clinical Course	Pathologic Condition	Treatment
1	Buschke [1]	1902	M	44 yrs	Influenza, erythematous eruption	Face, neck, thorax, gluteal region, lower limbs, 1 year later the cheeks remained indurated		Massage, iodides, salicylic acid
2	Baginsky, A Berl klin Wchnschr, 1903, no 19, Berl med Gesellsch **23**: 3, 1903	1903		5¾ yrs	General malaise	Neck, thorax, arms, tongue, improved gradually		Thyroid extract without results; baths, massage, heat
3	Halle Arch f Dermat u Syph **91**: 362 1908	1908	M	45 yrs	Influenza	Neck, arms, trunk		Massage, baths, a fibrin ferment
4	Rissom [1b]	1909	M	45 yrs	Influenza pyodermia of nipples and neck	Face, neck trunk, extremities, was still present after 2 years		Baths, massage, ointments, injections of a fibrin ferment
5	Nobl [4a]	1909	F	52 yrs	Bronchial catarrh	Face, neck, trunk improved greatly in 7 months		
6	Nobl [4b]	1911	F	20 yrs	Influenza 8 weeks later	Face, neck, trunk, arms, receded in 2 years		Baths, massage, salicylic acid, thiosinamine
7	Nobl [4c]	1911	F	6 yrs	Epidemic parotitis	Face, neck, trunk, severe anemia cleared in 8 months	Vessels of cutis dilated surrounded by numerous mast cells	
8	Nobl [4d]	1911	F	24 yrs	Influenza	Face, neck, thorax, upper extremities, hands not affected subsided after 10 months		A fibrin ferment subcutaneously
9	Nobl [4b]	1911	F	30 yrs	Influenza	Neck, trunk, arms		
10	Bamberger [1c]	1911		(a) 20 yrs	Influenza 2 days later	Face, thorax, breasts		Salicylic acid salve, massage, a fibrin ferment
				(b) 26 yrs	Influenza, recurrence	Face, thorax, neck, extremities, back, cleared in 2 years		A fibrin ferment and quartz lamp
11	Roscher Arch f Dermat u Syph **113**: 875, 1912	1912	M	22 yrs	Fever, herpes, nasal	Face, trunk, neck, arms	Wide spaces in connective tissue of cutis partially filled with transparent, poorly stained masses	Turkish baths, massage, a fibrin ferment

34	Rummert [6]	1929	F	13 yrs	Tonsillitis; pharyngitis	Neck, trunk, arms	Blood vessels dilated; perivascular cellular infiltration	Baths; a preparation containing solution of pituitary
35	Leané, E; Dryfus See, G, and Launay, C. Bull Soc de pédiat de Paris **27**: 518, 1929	1929	M	4½ yrs.	Tonsillitis; hemorrhagic nephritis	Back, face, thorax, thighs, arms involved; forearms, hands, feet and scrotum free; improved in 3 months and cleared gradually	.	Thyroid
36	Audry and Gradat [16]	1930	M	68 yrs	Rheumatic pains in lower limbs	Legs and thighs; a local inflammation present over legs; cleared in a few months	..	Potassium iodide, arsenic
37	Seifert, A: Arch f Kinderh **91**: 220, 1930	1930	M	6 yrs.	No preceding infection	Back, shoulders, abdomen and arms; receded in 5 weeks; (?) pituitary deficiency	.	Massage
38	Mayr [7] .	1930	M	44 yrs	Influenza	Neck, chest, back, abdomen, arms; improved in 5 months	Blood vessels normal; no mucous substance found between collagen bundles	Massage, baths, salicylic acid ointment
39	Mayr [7]	1930	F	26 yrs	Not stated	Neck, back, front of trunk and arms; incomplete cure *in 7 years; persistent thymus*		
40	Freund [8]	1930	F	57 yrs	Influenza	Face, neck, shoulders, arms, forearms, faded toward pelvic region; lower extremities, hands and wrists free	Three biopsy specimens taken about the same time; perivascular infiltration, mainly fibroblasts and round cells; vascular walls and nerves normal; edematous collagen fibers	Pituitary and thyroid extract, without avail
41	Freund [8]	1930	F	28 yrs	Mastitis and pharyngitis articular rheumatism 5 weeks after a normal delivery	Entire body except hands, feet, ankles and abdomen	Similar to preceding case	

The rigidity of the skin of the face and eyelids produces a masklike appearance. The patient frequently has difficulty in opening his mouth, and movement of the neck is restricted. The limbs may be flexed and extended with difficulty. Occasionally, owing to the rigidity of the wall of the chest, respiration may be interfered with, but never to a grave extent. In one of our cases the patient complained of this particularly after a full meal.

The disease is usually ushered in with symptoms of fever and malaise and follows some acute infection. Within a few days the induration develops as described, and the constitutional symptoms subside. The process recedes in from a few days to several years. In one of Hoffmann's cases,[9] the rigidity persisted for fifteen years, while in Kutter's case[10] it disappeared within eight days. The condition usually clears within the first year. There are no sequelae. In children the distribution of the process is usually more widespread, and the progress is more rapid than in adults.

Adler[11] and Bamberger[12] each reported recurrences of the disease. In both of my cases recurrences occurred. Laboratory investigation reveals nothing of significance.

ETIOLOGY

The etiology of scleredema adultorum is obscure. The frequency with which the induration follows some acute infection points strongly to a definite relationship. The infection usually precedes the onset of the scleredema by from a few days to a few weeks. In eighteen cases influenza preceded the condition. Three were ushered in with acute tonsillitis; three followed scarlet fever and two encephalitis; epidemic parotitis occurred in one and bronchial catarrh in one, while in five other cases symptoms of fever, malaise and weakness were reported. Seifert stated that a history of a preceding infection was not present in his case. In the two cases reported here the condition followed influenza in the first and tonsillitis in the second.

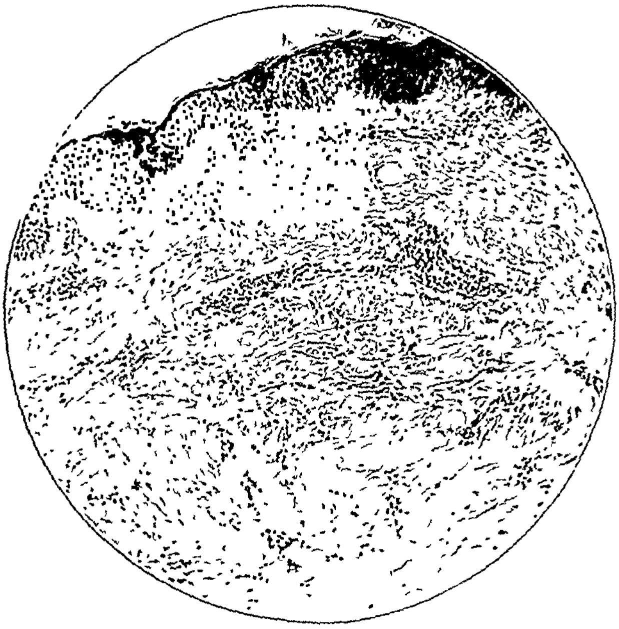

Fig. 2 (case 1).—Section under low power.

It is interesting to note that in two cases reported by von Graevenitz[13] impetigo contagiosa preceded the scleredema, and in the patient whose case was reported by Naegele[14] a pyodermia was present over the arms. In Rissom's case[15] there was a pyodermia of both nipples, and in the report of Audry and Gadrat[16] a dermatitis was present over the lower portion of the affected extremities. In this group of cases the induration usually began close to the site of the cutaneous infection.

The exact rôle that these acute infections play in the production of scleredema adultorum is not entirely clear. The fact that the induration frequently begins near the main source of the infection and progresses in a definite set manner in each case substantiates the theory of some writers that the condition is produced by a lymph block and is a type of elephantiasis. This is illustrated by the numerous instances in which there is an infection of the throat and the process begins in the neck. The cases which followed cutaneous infections also suggest this possibility.

No definite relationship could be found between disturbances of the endocrine glands and sclerema. In several instances in which thyroid and pituitary extracts were used for therapy no apparent benefit was obtained.

In thirty-five cases in which the sex was stated, twenty-two were female and thirteen male patients. The ages varied from 8 days to 68 years. The largest number of patients, namely, thirteen, were under the age of 10 years. Four were between the ages of 10 and 20 years, eleven between 20 and 40, nine between 40 and 60 and three between 60 and 70.

PATHOLOGY

The histopathology of scleredema adultorum, as reported by various workers, does not appear to be the same in all cases, but may vary at different stages of the disease. Freund[8] described the microscopic changes in detail.

The epidermis is little changed except for an occasional prolongation and widening of the rete pegs. In the corium there is a perivascular infiltration consisting mainly of connective tissue cells of the fibroblastic series and a few lymphocytes and plasma cells. The walls of the blood vessels have been reported thicker than normal in some cases, but for the most part have been found normal. There is no endarteritis. The nerves, sweat glands and hair follicles are unchanged. The elastic tissue is normal.

The most prominent feature is an enlargement of the collagen bundles to several times their normal size. This produces a thick layer in the deeper portion of the corium and throughout the subcutaneous tissue. The collagen bundles are edematous, and there are few connective tissue cells among them.

Histologically, most workers found spaces around the blood vessels and the epithelial appendages. In some areas these were filled with a well stained, transparent material. The nature of this substance is unknown, but it has been shown not to be mucin. Freund[8] expressed the belief that this material is produced either by the degeneration of connective tissue or by fibroblastic activity. In some respects it resembles the material found in myxedema.

Biopsies were done in both of the cases reported here and presented the following findings:

Case 1.—A biopsy specimen was taken from the right forearm two weeks after the onset of the disease.

The epidermis appeared normal. Just below the epidermis was a narrow strip of connective tissue which was relatively acellular and was composed of fine fibrils containing a few nuclei of fibroblasts. There was a perivascular infiltrate, which was also present about the sweat glands deep into the section. This infiltrate was composed mainly of fibroblasts with a few round cells. The blood vessels were normal.

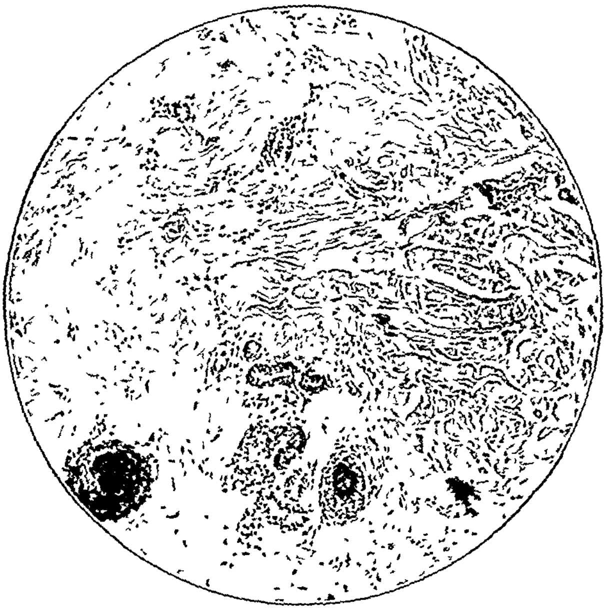

Fig. 3 (case 1).—Section deep in corium, under high power.

Swollen bundles of collagen tissue occupied the lower portion of the corium and subcutaneous tissue. The collagen tissue was markedly edematous and separated by vacant spaces which could also be seen about the sweat glands. In places the spaces contained a transparent, faintly staining material.

[15] Rissom: Arch. f. Dermat. u. Syph. **94**: 39-48, 1909.

[16] Audry, C., and Gadrat, J.: Ann. de dermat. et syph. **1**: 161-167 (Feb.) 1930.

The elastic tissue was normal.

Case 2.—A biopsy specimen was taken from the back of the right shoulder three weeks after onset.

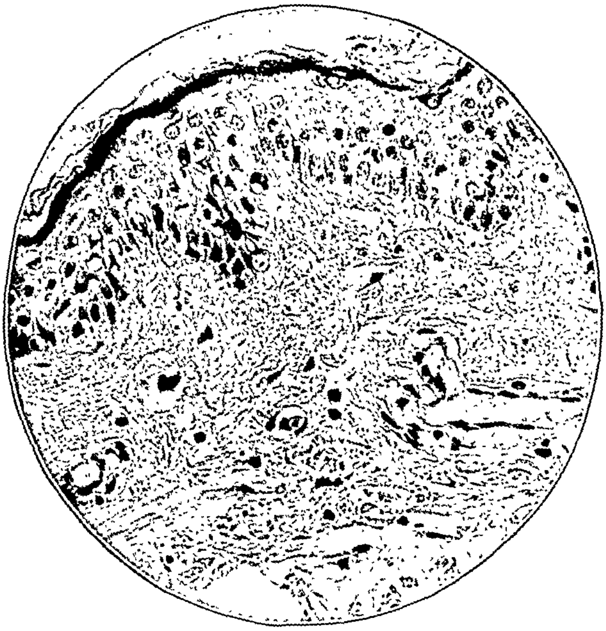

Fig. 4 (case 2).—Section of epidermis and upper corium, under high power.

The epidermis was normal. Beneath the epidermis could be seen a definite narrow band of connective tissue made up of fine fibrils and containing a few fibroblasts. This tissue was probably young connective tissue. A slight perivascular infiltrate composed of a few fibroblasts and a few round cells extended down with the blood vessels, sweat glands and hair follicles deep into the corium. This infiltrate was considerably less pronounced in this case than in case 1. The blood vessels were normal.

The deeper portion of the corium and the subcutaneous tissues were thickened to several times the normal and were occupied by greatly swollen collagen bundles. These bundles were separated and broken up by spaces which in many places contained a faintly staining, transparent material. This entire area was quite acellular, containing a few nuclei of fibroblasts.

DIFFERENTIAL DIAGNOSIS

Scleredema adultorum is to be distinguished from diffuse scleroderma, to which it bears a striking resemblance. Undoubtedly many cases of scleredema have been classified and reported in the literature as diffuse scleroderma. The essential differential points between scleredema and scleroderma may be summarized as follows:

1. In scleredema the epidermis is not affected, the process being in the deeper portions of the skin and subcutaneous tissue and occasionally the fascia and muscles, while in scleroderma the superficial skin layers are frequently involved.
2. Scleredema follows some acute infection, while scleroderma has no constant relation to infections.
3. Scleredema always involutes spontaneously without subsequent atrophy of the affected tissues, while scleroderma may end fatally and frequently results in atrophy of the affected parts.
4. The hands and feet are never affected in scleredema, while in scleroderma they are frequently involved, with the production of sclerodactylia. In scleroderma a syndrome simulating Raynaud's disease is often seen.
5. Pigmentary changes are absent in scleredema and frequently present in scleroderma.
6. Histologically, scleredema differs from scleroderma in that an inflammatory reaction is never a prominent feature, endarteritis is not seen, and atrophy never occurs.
7. Calcification of the skin or subcutaneous tissues, occasionally reported in scleroderma, never occurs in scleredema.

Myxedema, trichinosis, adiposis dolorosa, dermatomyositis and edemas of cardiorenal origin are readily distinguished from scleredema.

The possibility that sclerema is a form of elephantiasis must be kept in mind.

TREATMENT

Scleredema adultorum is a self-limited disease, the process involuting spontaneously within varying lengths of time.

Endocrine gland therapy has not been beneficial. Massage and hot baths are useful. The use of a 1 or 2 per cent salicylic acid ointment is recommended. Injections of a fibrin ferment have been used.

COMMENT

The two cases reported here are typical examples of scleredema adultorum. The onset of the condition in each patient after an acute infection, the gradual disappearance of the induration without atrophy of the skin or other sequelae and the histologic changes are characteristic of the disease.

A striking similarity in the clinical picture of these two patients was noted. The distribution of the induration was practically identical in the two. Each patient suffered from a recurrence of the condition. The first attack occurred at the age of 15 years in case 1 and at 16 years in case 2. The second attack occurred at the age of 31 in case 1 and at 43 in case 2. In both patients the second attack was more severe than the first, being more extensive and slower in receding. An associated

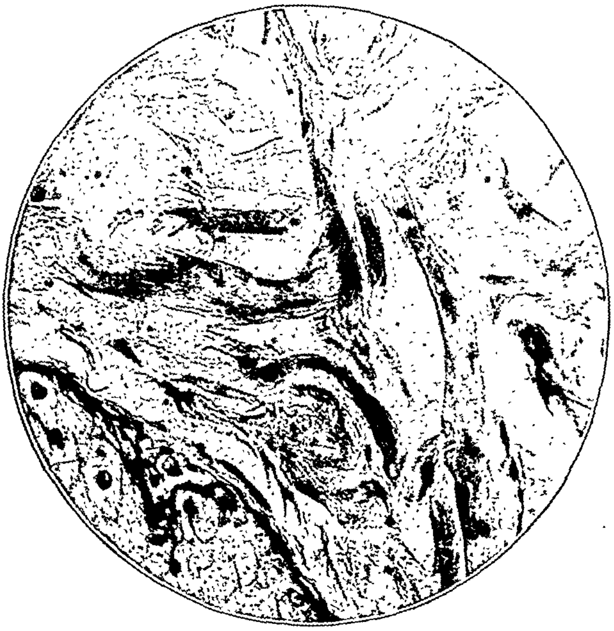

Fig. 5 (case 2).—Oil immersion view, deep in corium, showing edematous collagen and spaces.

tonsillitis was found in each case, eventually necessitating tonsillectomy. The use of thyroid gland therapy was of no benefit. In case 1 the induration was preceded by a transitory erythematous eruption in both attacks.

Scleredema adultorum is a distinct entity that has a definite clinical course and a characteristic histopathology. It is probably not as uncommon as the literature would indicate. Many cases are undoubtedly reported and classified as diffuse scleroderma.

The differentiation of this disease from scleroderma is quite important from the standpoint of prognosis and treatment.

450 Sutter Street.

ABSTRACT OF DISCUSSION

Dr. Harold N. Cole, Cleveland: I think Dr. Epstein's contribution is the first there has been in the American literature, and it is timely. If one looks in American textbooks today one will find no mention of scleredema adultorum. The term sclerema adultorum is also used for scleredema. Perhaps it is unfortunate to have such a close resemblance in the two names, but such is the case. There is no question that scleredema adultorum is a distinct entity, though I do believe that it may be due to a variety of causes. I agree with Dr. Epstein that there are a considerable number of these cases and that in the past proper diagnoses have not been made. I recall one typical case of this seen in a child, aged 10 or 12 years. The child had but recently recovered from scarlet fever. The picture was the exact counterpart of the disease described by Dr. Epstein. I think that probably the pediatricians see more of these cases than the dermatologists but that if we watch for them in the future, we shall find that the disease is not so rare.

Dr. Fred D. Weidman, Philadelphia: I think that when more is finally known about the chemistry of the substance that is responsible for the horny condition of this skin it will be found not to be a constant thing. I think that in some cases it will turn out to be a mucoid material and have some relation to thyroid disease, as in localized cases of myxedema. I have found that in some cases the material was more amyloid in its microchemical reactions. In these cases one should examine for the internal changes which may lead on the one hand to mucoid changes and on the other hand for such things as malaria, chronic suppuration, and all the other conditions that may lead up to amyloid disease. I think it is a clinical entity, but just as zoster has many different causes, so does this, and the type of the disease depends on the microchemical composition of the substance that is responsible for the cutaneous condition.

Dr. George M. MacKee, New York: There is a type of sclerema occurring in children that is called sclerema neonatorum. This follows one of the acute exanthems. It undergoes a rapid course and ends in complete recovery. That condition is quite different from the other type, which leads to death. I should like to ask Dr. Epstein whether the adult scleredema is not identical with or similar to this particular type of sclerema neonatorum.

Dr. Norman N. Epstein, San Francisco: Buschke emphasized the similarity between scleredema adultorum and the sclerema neonatorum. He gave the disease this name because of the resemblance. The name perhaps is not the best, because most of the cases fall in the age group below 10 years.

Treatment of Placenta Praevia.—Each individual case must be carefully considered. Just as illegitimate as the fundamental condemnation of cesarean section is to be considered nowadays, just as regrettable and exaggerated does the attitude seem to me that is taken up by some accoucheurs who, in point of principle, will use cesarean section in all cases of placenta praevia. I may once again draw attention to the fact that out of my 240 patients not less than 95 were delivered spontaneously or after puncture of the membranes, with one fatal case only. Would anybody insist that these mothers should have been subjected to cesarean section?—Essen-Moller, Elis: *J. Obst. & Gynaec. Brit. Emp.* **39**:231 (summer) 1932.

FORCED SPINAL DRAINAGE IN ITS RELATION TO INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

GEORGE M. RETAN, M.D.
SYRACUSE, N. Y.

In 1919, Weed and McKibbon[1] demonstrated that the intravenious injection of a hypotonic solution increased the intracranial pressure. In 1923 and 1924, Weed[2] found that the intravenous injection of a hypotonic solution in animals caused a hydrosis of the central nervous system. The essential changes were a hydrosis of the cells in the choroid plexus, a collection of fluid in the perineural spaces, a dilatation of the perivascular channels that lead into the subarachnoid space and an increased intracranial pressure.

In 1928, Kubie[3] demonstrated that if a hypotonic solution is injected into the blood stream of animals there is a marked increase in intracranial pressure and a striking hydration of the central nervous system. If, however, a needle is introduced into the subarachnoid space and the increased fluid is allowed to drain, there is no rise in intracranial pressure and no hydrosis of the central nervous system results. He concluded:

> It is evident that lowering the osmotic pressure of the blood with a hypotonic solution causes a transudation of fluid from the capillaries in the perivascular and perineural areas throughout the whole central nervous system; and that by similarly draining the cerebrospinal fluid a free escape of this transudate is accomplished from the depths of the tissue to the surface through the pathway of the least resistance.
>
> In this way a washing out of the perivascular exudates into the subarachnoid space was achieved in meningo-encephalitis in cats.

In support of Kubie's findings, I have performed four autopsies in cases of septic meningitis in which forced spinal drainage was done, and no hydrosis of the central nervous system was found, either in the gross or microscopic sections.

Kubie further suggested the possible use of this method of treatment in human beings.

The change in osmotic pressure produced by the intravenous injection of a hypotonic solution is a powerful physiochemical force. Loeb and Roth,[4] indeed, stated that the osmotic pressure even of physiologic solution of sodium chloride is about 4.9 atmospheres.

The action of such a solution is shown in the diagram. The capillaries are represented by *C*. There is a flow of fluid from the blood stream through the capillary wall into the intercellular spaces (*I*). The fluid flows through the intercellular spaces to the perivascular space (*P*), thence to the subarachnoid space (*S*) and the lumbar needle. In this manner one is able to lave nerve cells in the depths of the tissue of the central nervous system.

There is a further fact of the greatest importance. Wherecever inflammation exists there is an increased collection of fluid in the pericellular lymph spaces. This constitutes the phenomenon of edema. Although

the mechanism of edema resulting from inflammation is not thoroughly understood, it is known that there is an increased permeability of the capillary walls. Since the capillaries in the inflamed area are more permeable to interchange of fluid, the decreased osmotic pressure of the blood stream is exerted principally at the point of least resistance, which is the inflamed area. This is illustrated in the following cases:

Case 14.—An infant, aged 9 months, had tuberculous meningitis and acute colitis. The colitis resulted from catharsis. During the intravenous injection of 2 liters of hypotonic solution, a quantity of fluid was eliminated every fifteen or twenty minutes from the colon.

Case 15.—This is a case of clinical tuberculous meningitis. The patient, a child of 3 years, developed some type of urinary infection with frequent and burning urination and pus in the urine. Eighteen hundred cubic centimeters of a solution of 0.45 per cent sodium chloride was injected into the vein. There resulted a prompt diuresis of from 60 to 80 cc. each ten minutes, with no increase in the flow from the spinal needle. One-half cubic centimeter of solution of pituitary was injected into the muscle followed by a marked decrease in urinary output and an increased flow of spinal fluid.

Case 18.—This is a case of influenzal meningitis with bronchitis. When the hypotonic solution was injected, bubbling râles were produced throughout the chest.

In infections of the central nervous system, having as a basic pathologic process a perivascular round cell infiltration, one invariably finds an increased number of round cells in the spinal fluid following the introduction of a hypotonic solution into the blood stream. Kubie[3] found this increase in animals in which meningitis was experimentally produced. The same phenomenon was observed in both of my cases of poliomyelitis, in one of acute encephalitis (in the other case the fluid was bloody), in two of chorea, in three of tabes and in one case of chronic encephalitis of the parkinsonian type of four years' duration (tables 1, 2, 3, 4, 5, 6 and 7).

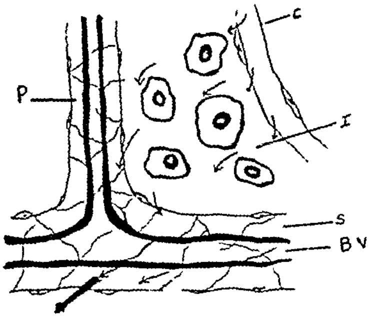

Diagram showing fluid pathways in the central nervous system during forced spinal drainage.

In tabes I have found that after the introduction of a hypotonic solution into the blood stream, the globulin content of the spinal fluid increases from about 15 to as high as 98 mg. per hundred cubic centimeters.

These various facts lead to the following conclusions: When the osmotic pressure of the blood is lowered, the resultant force is exerted selectively on the inflammatory areas. Products of inflammation are washed from the depths of the affected areas to the surface.

Forced spinal drainage relieves the edema which is a part of the pathologic process in these various infections. In cases of poliomyelitis the tremor disappears. In tabes I invariably find changes in nerve reactions immediately following the treatment. One tabetic patient regained the sphincter control of his bladder after having been incontinent for four years; changes in the reflexes and in sensory disturbances are found. These changes are immediate and can be explained only on the basis of a lessened edema.

For purposes of discussion I shall separate the infections of the central nervous system into two groups. In the first group I include those infections the basic pathologic process of which is a perivascular round cell infiltration. These diseases are Sydenham's chorea, acute and chronic epidemic encephalitis, preparalytic poliomyelitis, syphilis of the central nervous system and tuberculous meningitis. These various infections exhibit individual differences in their pathologic process but in a general way are similar. They first affect an inflammatory reaction of the meninges with a subsequent invasion of the deeper tissues of the central nervous system. Hemorrhage, edema and necrosis play their rôle in most of these diseases. Perivascular infiltration, edema and hemorrhage are, of course, of vascular origin, and necrosis is due to the action of the various toxins on tissue and may also be caused by circulatory disturbances from the edema. Forced spinal drainage is most effective in this group of diseases, to which this paper will be limited.

SYDENHAM'S CHOREA

The few cases of acute chorea that have been examined at autopsy show small localized areas of perivascular round cell infiltration. The infection is not a

The rigidity of the neck subsided gradually but was not entirely gone until December 14. The patient made a gradual convalescence and was discharged from the hospital January 6, fully recovered.

I am presenting this case as a proof of the safety of forced spinal drainage. This child received eighteen days and nights of treatment without developing symptoms attributable to the drainage except for an intermittent headache and an occasional vomiting, both of which were easily controlled. The only reasonable clinical diagnosis was tuberculous meningitis, but bacterial confirmation was lacking.

* R indicates recovered; I, improved; N.I., no improvement, and D, death.

Prior to the publication of my first case reports on forced spinal drainage, there had appeared in the literature one case report in which this method was used. Casten[7] used forced spinal drainage in the treatment of tryparsamide amblyopia with complete success.

Fremont-Smith[8] and his co-workers used a modification of this method in the treatment of multiple sclerosis, giving a continuous drainage of the lumbar sac for from four to six hours. From 500 to 1,000 cc. of water was given by mouth per hour. Diuresis was delayed by an injection of 0.5 cc. of pitressin. While this method may reduce the osmotic pressure of the blood to some slight extent, I feel that the force is not sufficient to wash fluid through the intracellular spaces in the central nervous system.

Spurling[9] reported eight cases in which continuous spinal drainage was used. He performed a lumbar laminectomy followed by large amounts of water by mouth. One patient with poliomyelitis of six days' duration (a flaccid paralysis of the lower part of the body extending upward to include the intercostals and one leaf of the diaphragm) recovered. Spurling included four cases of septic meningitis with three recoveries and two of brain abscess with one death.

I am confident that forced spinal drainage cannot be done successfully without the injection of a hypotonic solution into the blood stream. At least 1 liter of 0.45 per cent sodium chloride solution should be injected, over an hour's time. In the more severe cases this injection must be given repeatedly. Clyses of physiologic solution of sodium chloride and water by mouth act as adjuncts to the intravenous injection, but only after this has been given. Fluid pathways through inflammatory tissue once established are easily maintained, but they are established only by an intravenous injection of hypotonic solution.

It is essential that the spinal fluid drip from the lumbar needle during the injection of the hypotonic solution and for at least an hour after it is given. If the drip ceases for any reason, the injection must be stopped until the drainage has been reestablished.

An occasional headache may develop but can be relieved by introducing the style into the needle for ten or fifteen minutes. Patients may rarely vomit, and this is not an indication to interrupt the treatment. Otherwise there have been no untoward symptoms in any of my cases. I am convinced that this treatment can be given with perfect safety. This conviction is based on over two thousand hours of forced spinal drainage given in twenty-two cases without any alarming symptoms.

SUMMARY

Forced spinal drainage was used in twenty-one cases of various infections of the central nervous system.

In four autopsies in cases of septic meningitis no hydrosis of any organ was found.

There was evidence of a washing of fluid through inflammatory areas.

Products of inflammation were washed from the depths of affected areas.

The field of greatest usefulness for forced spinal drainage was in diseases of the central nervous system characterized by perivascular round cell infiltrations.

Forced spinal drainage was shown to be a safe procedure. Over two thousand hours of treatment have produced no alarming symptoms.

ABSTRACT OF DISCUSSION

DR. H. WARD WILLIAMS, Rochester, N. Y.: Because of unsatisfactory results obtained with the Fremont-Smith method of spinal drainage in meningitis, I attempted to do a laminectomy in these cases. I had the distressing experience of having an abscess, secondary infection, occur back of the suture line of the laminectomy, with eventual death from that cause. In attempting to find some other method, it occurred to me that a laminectomy could be made with a small opening and might prove satisfactory. I succeeded in working that out. Though it is too early to say what is going to happen, it seems that the results have been highly satisfactory with that small laminectomy done through the speculum.

DR. GEORGE M. RETAN, Syracuse, N. Y.: I have been asked to say a word about the technic. After the lumbar puncture, the patient is placed on a Bradford frame with a window cut in the lumbar region. I believe that there is some hope in cases of septic meningitis. The difficulty has been insufficient drainage from the sac. In these cases drainage must be done from the lumbar sac because it is the lowest point of gravity. I have a special needle for this purpose.

---

[7] Casten, Virgil: New England J. Med. **202**: 676 (April 3) 1930.

[8] Fremont-Smith, Frank; Putnam, T. J., and Cobb, Stanley: Forced Drainage of the Central Nervous System, Arch. Neurol. & Psychiat. **23**: 219 (Feb.) 1930.

[9] Spurling, R. G.: Kentucky M. J. **26**: 242 (May) 1928.

The needle has a removable head so that it can be inserted, the head removed and a larger needle introduced over the smaller one. The first needle is then removed. This gives a freer drainage. In the treatment of septic meningitis, this needle is introduced first. If the patient improves, a lumbar laminectomy must be done because the drainage must be free every minute. That is the mistake that has been made in the past—not getting drainage free enough.

Clinical Notes, Suggestions and New Instruments

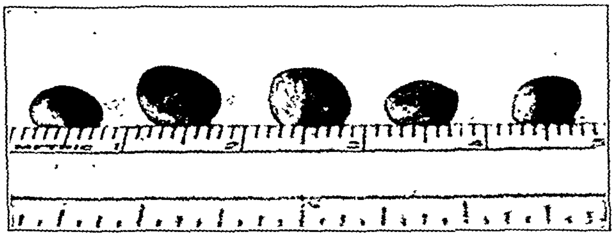
PHIMOSED PREPUTIAL SAC SERVING AS AN ADVENTITIOUS URINARY RESERVOIR

THOMAS V. WILLIAMSON, M.D., NORFOLK, VA.
Senior Staff Urogenitologist to Protestant, St. Vincents and Memorial Hospitals; Consulting Urogenitologist to the United States Veterans' Bureau

This case was unusual in that the preputial orifice was so greatly phimosed that a small quantity of urine always remained within the preputial sac, while at the same time five small, smooth and fairly round uric acid calculi were found entrapped therein.

A Negro boy, aged 15, presented himself in June, 1931, with the complaint of painful and difficult urination.

The patient was of the arrested mental development type and appeared to have the wit of a child of 10. The parents being absent at the time of the examination, no dependence could be placed in the past history. No information relating to urinary calculi could be elicited.



Calculi removed from preputial sac.

The boy had been having trouble in voiding the urine for some years. In the past six months the difficulty had been vastly increased; there was much soreness in the region of the glans penis, together with burning pain during and immediately after the act of urination. He stated that the urinary stream was quite small and that it took a long time, comparatively speaking, to complete the act.

The patient was tall, lanky and undernourished, and had a silly, vapid expression. Examination did not disclose anything pertinent to this report except on the penis.

The penis was very large for the age of the boy and there was much redundance of the foreskin. The orifice of the prepuce was phimosed to the extent that it would not admit an instrument larger than number 6 F. The tissues around the orifice were hard and thickened, and they presented the aspect of having been the seat of recent ulceration.

When the patient attempted to void, the redundant prepuce was seen to balloon out with urine to the size of a large lemon. The stream of urine was little more than a jet and had considerable force, being propelled for a distance of several yards. This urinary tumor within the preputial sac persisted until the act of voiding was completed; then it subsided slowly as the urine dribbled out. The sac was not completely emptied, however, as several drachms of fluid remained trapped within it. This residual urine was enough in quantity, when mingled with smegma, to constitute an irritating medium capable of inducing the pain and irritation suffered by the patient.

Several small, hard masses were felt within the preputial sac. These masses were freely movable, appeared to be entirely separate one from the other, and gave rise to a grating, calcareous sound on being rubbed together.

The operation consisted of circumcision. The fibrous tissue around the preputial orifice was almost cartilaginous in consistency and required forceful cutting with the scissors to divide. There were five dark brown bodies resembling uric acid calculi lying loose within the sac. They were fairly regular in outline and, for the greater part of their surfaces, smooth. This comparative roundness and smoothness seemed to be due to the fact that they had been able to move about freely and, in doing so, had rubbed against one another. This regularity of contour is a characteristic of all calculi that move around freely in a cavity such as the urinary bladder.

The inner surface of the prepuce was regular and glistening as though it had been kept polished by the passage of the imprisoned calculi passing back and forth over it. The glans penis was the seat of chronic inflammation and was irritated to a painful degree. The urinary meatus in the glans penis was smaller than normal and would not permit the calculi to be reintroduced into it.

Since the calculi were all too large to reengage in the urinary meatus, they evidently grew in size after they had passed from the bladder into the preputial sac. It may be that the residual urine within the preputial sac had been sufficient in quantity to permit this phenomenon, and it seems that the sac was never entirely empty unless the patient pressed the residue out. It may have been that the stones were developed in their entirety beneath the prepuce, particles of smegma acting as the central nuclei. The central parts of uric acid calculi are often porous and poorly organized, so that it is impossible to know definitely what the nuclei may have been at the beginning of the calcareous formation.

In this case the preputial sac was clearly an adventitious reservoir.

SPONTANEOUS RUPTURE OF AN APPARENTLY NORMAL SPLEEN

VINCENT J. DARDINSKI, M.D., WASHINGTON, D. C.

Spontaneous ruptures of the spleen are divided into two distinct groups: those occurring in an organ which is in any way altered from the normal, and those in which the spleen appears to be normal on macroscopic and microscopic examination.

Among the more common causes of rupture in the former group may be listed, in the order of frequency, according to Berger's[1] statistics, malaria, trauma, pregnancy (usually in cases in which the spleen was already diseased), typhoid, leukemia, syphilis, alcoholic cirrhosis, tuberculosis, hemophilia, capsular varices, typhus, anemia, eclampsia, relapsing fever, infarct, abscess and aneurysm. Among these Besnier[2] includes also epilepsy and purpura.

The causes of rupture in apparently normal spleens are not understood, and judging from the literature opinions are scarce. This, I believe, is due to the fact that such cases are rare and the material available for study is still more rare.

Up to the present there have been reported in the literature fourteen cases, exclusive of the present one, which appear to be fairly authentic reports, with the possible exception of the cases of Skerritt[3] and Atkinson,[4] which might be considered doubtful because of the very brief reports.

All these cases have been reviewed recently by Bailey[5] and Byford,[6] so another review of them at present is not necessary; but there are so few cases of this nature reported that I will include here a list of them in order to have the literature on this subject as complete as possible. Cases have been reported

I believe that the present case is worthy of reporting because of the evidence suggesting the etiology of rupture

REPORT OF CASE

C C, a Negro, aged 40, admitted to Georgetown University Hospital, Jan 25, 1932, in the morning, complained chiefly of pain and swelling in the right upper abdominal quadrant and of shortness of breath

His present illness dated back to six weeks before admission, at which time he noticed a gradual loss of strength with occasional "dizzy" spells and pain in the right upper quadrant which had gradually increased in severity He had had slight dyspnea for the past five or six years, which had become more prominent in the past six weeks

His past and family histories were essentially negative except that the patient had been a hard drinker ("corn liquor") the greater part of his life

Examination revealed temperature 97 6 F , pulse 70, blood pressure 96 systolic and 74 diastolic, respirations 20 A systolic murmur was present over the second right interspace A large, tender, nodular mass was palpable in the right upper quadrant, and there was edema of the soft tissues of the abdomen Examinations of the blood and urine were not made The chemical examination of the blood revealed a nonprotein nitrogen of 64 mg per hundred cubic centimeters A kidney function test at the end of two hours was 30 per cent

At noon of the day of admission, while lying quiet in bed, the patient complained of a sharp, severe, sudden pain in the left side, in the lower costal margin, which gradually subsided but left him more dyspneic A dull ache persisted in this region until the third day after admission, at which time he became more dyspneic and complained of a sharp lancinating pain in the same region in which he experienced his first attack of pain This time, however, the pain did not remain localized in the left lower thoracic region in the midaxillary line but radiated upward, involving the left shoulder Following this complaint, the patient gradually developed all the symptoms and signs of shock, from which he never recovered He died three and one-half hours after complaining of pain in the left shoulder

The cause of death in this case was not suspected, but it was believed to be due to myocardial failure

At necropsy, both sclerae were moderately jaundiced The abdomen was distended and dull on percussion A healed scar 10 cm long was found in the right upper abdominal quadrant, which was at a right angle to the midline This was the result of a stab wound The extremities were not edematous

When the peritoneal cavity was opened, about 3,000 cc of fluid and clotted blood was found The blood clots were located in the upper portion of the abdominal cavity beneath the left lobe of the liver, completely filling the left upper quadrant

To avoid any misinterpretation of the hemorrhage, the spleen and surrounding organs were thoroughly investigated before any of the organs were removed

The spleen was found to be free from adhesions and was of normal size In the border of the lower pole could be seen a break in the capsule 2 cm long, extending from the convex surface over onto the concave medial surface On removal the spleen weighed 160 Gm and the capsule was of a normal slate color The capsule was markedly wrinkled On section it was dark red and the pulp was slightly softer than normal The markings were slightly indistinct No subcapsular or intrasplenic hemorrhages were found

Of the other organs that might have some bearing in this case is the liver It was greatly enlarged, weighing 3,725 Gm Its surface was irregularly nodular, produced by hard white elevated nodules, varying in size up to 3 cm Similar nolules were present throughout the entire substance of both lobes

The *anatomic diagnosis in this* case was spontaneous rupture of an apparently normal spleen with primary carcinoma of the liver

Microscopic examination of sections from these organs revealed a malignant hepatoma of the liver and apparently normal spleen

COMMENT

The history and observations in this case are reported in some detail for two reasons First, this is the fifteenth case of spontaneous rupture of an apparently normal spleen to be noted Second, I wish to enumerate a few of the signs and symptoms which appear to be fairly characteristic of this condition A sudden, sharp, severe pain in the left lateral lower thoracic region is usually the first complaint Often this complaint is unheeded because the initial pain gradually subsides, except for *some indefinite dull ache in the region of the spleen* Sooner or later, however, pain returns, more severe than before, and radiates to the left shoulder region (Kehr's sign [16]) This is particularly true in the cases in which a subcapsular hematoma had been formed prior to rupture into the peritoneal cavity

Ballance's sign [16] is another interesting finding often present in these cases which is seldom elicited It is an increasing area of dulness on percussion in the left flank, which seldom shifts when the position of the patient is shifted, as it does in bleeding from other intra-abdominal structures This is believed to be due to the more rapid coagulation of blood coming from the spleen as compared with blood from other tissues [16]

The rupture of the spleen in this case can probably be accounted for by an increase of pressure within the organ produced by a damming back of blood from the liver Evidence of this was found in the marked wrinkling of the capsule, which was produced by the escape of blood from the organ and a return to its normal size

CONCLUSIONS

1 The initial symptom of sudden, sharp, severe pain in the left lower lateral thoracic region is suggestive of splenic rupture

2 The presence of Kehr's and of Ballance's sign constitutes a fairly definite diagnostic aid

3 Evidence as to etiology is suggestive in a normal sized spleen with a markedly wrinkled capsule

Committee on Foods

GENERAL COMMITTEE DECISIONS

The Committee on Foods authorizes the publication of the following General Committee Decision adopted for its own guidance and for that of food manufacturers and advertising agencies on food advertising

Raymond Hertwig, Secretary

ANALYTIC STATEMENTS ON LABELS AND IN ADVERTISING

Analytic statements on labels and in advertising shall be expressed in such terms as will enable correct technical and popular interpretation and be properly and truthfully informative Listed analytic components shall be named in conformity with the methods used in their determination and preferably those of the Book of Methods of the Association of Official Agricultural Chemists The percentage values should be expressed in figures with significance only Proximate analytic statements for foods expressed to the units or the first decimal place only are in keeping with good analytic practice, in many instances the first decimal place is the limit of significance, in others the units place only is of practical significance percentage figures for the mineral elements, however, may extend to the second or third decimal place and in special cases even further

Analytic statements in advertising shall be simply and correctly informative and shall neither directly nor by connotation confuse or mislead those not specially informed in technical or scientific knowledge

REPORTS OF THE COMMITTEE

The following products have been accepted by the Committee on Foods of the American Medical Association following any necessary corrections of the labels and advertising to conform to the Rules and Regulations The products are approved for advertising in the publications of the American Medical Association and for general promulgation to the public They will be included in the Book of Accepted Foods to be published by the American Medical Association

Raymond Hertwig, Secretary

DAVIDSON'S DAINTY ROLLS

Manufacturer—Davidson Baking Company, Portland, Ore

Description—White rolls made by the sponge dough method (as described in The Journal, March 5, 1932, p 817), prepared from patent flour, water, sucrose, shortening, sweetened condensed skimmed milk, butter, yeast and a yeast food containing calcium sulphate, ammonium chloride, sodium chloride and potassium bromate

Analysis (submitted by manufacturer)—

	per cent
Moisture (entire rolls)	27 3
Ash	0 7
Fat	6 2
Protein (N × 6 25)	11 0
Crude fiber	0 5
Carbohydrates other than crude fiber (by difference)	54 3

Calories—3 2 per gram, 91 per ounce

FOODTOWN WHEAT POPS

(Flavored with Malt, Sugar and Salt)

Manufacturer—Foodtown Kitchens, Inc, Chicago

Description—Popped and toasted whole wheat flakes made from cooked whole wheat, flavored with malt extract, sugar and salt

Manufacture—Cleaned whole white wheat is cooked under steam pressure with a definite quantity of water in a rotary cooker and is flaked between rolls into thick flakes, which are dried by hot air in a "flight drier" to a definite moisture content A solution of malt syrup, sugar and salt is sprayed over the flakes, they are redried to a definite moisture content and are toasted in a rotary oven, which causes the starch cells to explode and puff the flakes into "wheat pops" in much the same manner as pop corn is popped The wheat flakes pass over "scalpers" to remove broken flakes The final wheat pops are packed in paraffin liners in paper cartons by automatic packing machines

Analysis (submitted by manufacturer)—

	per cent
Moisture	4 8
Ash	3 2
Chlorides as sodium chloride	1 9
Fat (ether extract)	1 3
Protein (N × 5 7)	9 8
Crude fiber	2 1
Reducing sugars as dextrose	0 9
Sucrose (acid inversion and copper reduction method)	6 4
Carbohydrates other than crude fiber (by difference)	78 8

Calories—3 7 per gram, 105 per ounce

Claims of Manufacturer—Ready to eat "popped" cooked and toasted whole wheat flakes supplying cellulose bulk to the diet as an aid to dietary laxation or regulation

UNION BRAND CRYSTAL WHITE TABLE SYRUP

(Corn Syrup and Granulated Sugar Syrup Flavored with Vanilla)

Distributor—Union Sales Corporation, Columbus, Ind

Description—A table syrup, corn syrup sweetened with sucrose, flavored with vanilla

Manufacture—A blend of corn syrup and sucrose syrup flavored with vanilla extract The manufacture is essentially that described for Pennant Crystal White Syrup (The Journal, Jan 30, 1932, p 402)

Analysis (submitted by manufacturer)—

	per cent
Moisture	25 5
Ash	0 3
Fat (ether extract)	0 0
Protein (N × 6 25)	0 1
Reducing sugars as dextrose	29 3
Reducing sugars as dextrose after invertase inversion	39 8
Reducing sugars as dextrose after acid hydrolysis	75 3
Sucrose	10 2
Dextrins (by difference)	34 6
Titratable acidity as HCl	0 01
Sulphur dioxide as SO	0 001
pH	4 9

No methods are available for accurately determining the composition of syrups of this nature, therefore the foregoing analysis is roughly approximate

Calories—3 0 per gram 85 per ounce

Claims of Manufacturer—A syrup for cooking, baking and table use and a carbohydrate supplement for milk modification for infant feeding

AUGUST NUTRITION BREAD

(Wheat and Rye Flours and Bran)

Manufacturer—August Bakery, Central Falls, R I

Description—A bread prepared by the straight dough method (method described in The Journal, March 12, 1932, p 889) from wheat and rye flours, wheat bran, water, malt extract, vegetable fat, salt, potato flour, yeast, powdered caraway seeds, and a yeast food containing calcium sulphate, ammonium chloride, potassium bromate and sodium chloride

Analysis (submitted by manufacturer)—

	per cent
Moisture (entire loaf)	32 0
Ash	2 4
Fat (acid hydrolysis method)	2 7
Protein (N × 6 25)	7 9
Crude fiber	0 9
Carbohydrates other than crude fiber (by difference) .	54 1

Calories—2 7 per gram, 77 per ounce

Claims of Manufacturer—This bread supplies cellulose bulk to the diet as an aid to dietary laxation or regulation

BABY'S CHOICE EVAPORATED MILK

(Sterilized, Unsweetened)

Manufacturer—Oatman Condensed Milk Company, Dundee, Ill

Distributors—Cardinal Milk Sales Company, Dundee, Ill

Description—This is the same evaporated milk as Oatman's Brand Evaporated Milk (The Journal, April 16, 1932, p 1376)

MORE ABOUT FOOTBALL—AND HEALTH

Those who have followed the unusual discussion that has attended the exposures of the dangers of football and the fatalities of the 1931 season find amusement in the unyielding championship of the game, as it has been played, that persists in the collegiate world. One undergraduate paper shrieks that "football is no sport for the soft and the yellow. It draws on nerve, determination, and common 'guts.' There is a long grind, a systematic elimination, and a final realization that 'all that glisters is not gold.' That is life. Life is going to be an unpleasant surprise to some sheltered scholars. It is a dirty business that draws on nerve, determination, and common 'guts.' " Then follows a flamboyant appeal based on the nation's need of men who know literally how to "give until it hurts"—not just scholars. The writer proceeds to remind the detractors about the kind of men the nation is seeking today: "Fighters, who do not flinch at disagreeable work, long grinds, increasing devotion to their ideals—come what may. They are the kind of men who, when young, play football, follow the crew grind the year round, train hard for track, or basketball, or hockey. Sports played hard against disappointment, in the cold and in the rain, are putting the steel fiber in character. They are building up the physical machine by rough tempering."

Somehow such outbursts are reminiscent of statements made by some physicians who urge that sickness and pain develop character in patients. Sickness, like scholarship in the colleges, thus becomes a mere incident in the daily job. Curiously enough, the rising tide of criticism of collegiate football still seems to be less concerned with the sanctity of the healthy body than with the impact of the game, as now conducted, on other human values. A fearless player has even boldly asserted[1] that "football is not a game; it is an activity. It is not a form of recreation in which students can vent their healthy animal spirits, etc. It is so far removed from sport that the very idea of playing without complicated secret signals and plays, well rehearsed through weeks of practice, is absurd. Those boys who take football as a means of personal exercise and enjoyment, when and how they will, are tragically foreign to the modern spirit of football and they not only do not get any play out of those days they go out for practice, but they also lose the benefits of the ballyhoo that falls to those who with some success do obey the letter of the coaches' law."

Dean Gauss[2] of Princeton, an experienced observer of college students, has recently admitted that the undergraduate attitude toward football is changing. He regards it as significant, however, that "nowhere in undergraduate circles is the game criticized because it is too rough. It is criticized because it has been commercialized and professionalized. The undergraduate protests because he feels that football, as now conducted, so-called big-time football, does not fit into his changed perspective. He is nowhere demanding that it be abolished, but that it be conducted less as a big business and in larger measure as a sport by and for undergraduates."

The situation in regard to collegiate football is in some way not unlike that which characterized "hazing" in the colleges a generation ago. When sport plays wantonly with health, not to say life itself, it must be reformed. Dean Gauss has pointed out that formerly in the colleges throughout the country, at least a few freshmen were annually done to death in the often vicious initiations into college life or college fraternities. This certainly was regrettable and this quite as certainly has disappeared in 1932, in favor of "emotional controls approved by society." During the season for which practice is soon to begin, football ought to bring no further reminders of the necropsy room. Fortunately, enforcement of the new rules indicates the elimination of some of the hazards so obvious last year.

PITUITARY BASOPHILISM

Of all the fields of medicine today, endocrinology particularly has lent itself to speculation. Innumerable syndromes of polyglandular type have been described. A polyglandular syndrome is apparently nothing more than a group of secondary functional alterations occurring in the ductless gland series whenever the activity of one of the glands has become primarily affected. Further, the term as employed is restricted to those cases in which it is difficult to tell where the initial fault is located. Examples of diabetes in bearded women, of rapidly acquired obesity, of hypertension, of masculinization in the female and of sexual precocity in children of either sex, often associated with hyperplasias or tumors of one sort or another of the suprarenal glands, have been many and varied. That a primary derangement of the pituitary gland, whether occurring spontaneously or experimentally produced, is particularly prone to cause widespread changes in other endocrine organs has been known for a long time. Indeed, it has been strongly suspected that this centrally placed and well protected structure in all probability represents the master gland of the series. These derangements have been found to be associated either with a destructive lesion or with a tumefaction primarily involving one or another of the organs in question. These tumefactions have proved in most cases to be of an adenomatous character. Finally, it was recognized (first in the case of the thyroid) that adenomas of this kind were functionally active structures that produced hypersecretory effects. It then gradually came to be realized that the tumor need not necessarily be bulky but, quite to the contrary, striking clinical effects might be produced by minute adenomas. Hence it is the degree of secretory activity of an adenoma which may be out of all proportion to its dimensions that evokes the recognizable symptom complex in all hypersecretory states.

---

[1] Yale Alumni Weekly **41**: 513 (March 25) 1932.

[2] Gauss, Christian: A New Type of College Youth Evolves, New York Times Magazine, April 3, 1932.

Recently Cushing[1] has described a series of fourteen cases of basophilic adenomas of the pituitary gland and the associated symptom complex. The features observed in all the cases are (1) a rapidly acquired, peculiarly disposed and usually painful adiposity confined to the face, neck and trunk, the extremities being spared; (2) a tendency to become round shouldered (kyphotic), even to measurable loss of height, associated with lumbospinal pains; (3) a sexual dystrophy, shown by early amenorrhea in women and an ultimate functional impotence in men; (4) an alteration in normal hirsuties, shown by a tendency to hypertrichosis of the face and trunk in all the women as well as in the preadolescent male; (5) a dusky or plethoric appearance of the skin with purplish lineal atrophic areas; (6) vascular hypertension; (7) a tendency to erythremia, a count exceeding five million having been present in five of the cases in which blood counts were recorded; (8) a peculiar softening of the bones due to an increase in calcium output; (9) hyperglycemia; (10) variable backaches, abdominal pains and ultimate extreme weakness. Other features less consistently recorded have been purpura-like ecchymoses, whether from bruising or occurring spontaneously, aching pains in the eyes, polyphasia, polydipsia and polyuria, and a susceptibility to pulmonary infections.

In most of the cases described the condition occurred in relatively young adults, the patients were definitely undersized, and the average duration of the disease from onset to death has been slightly over five years. The syndrome is not uncommon. Numerous typical examples have been reported, the disease in most instances having been ascribed to a primary suprarenal disorder, for the reason that cortical suprarenal hyperplasia is a not uncommon postmortem observation. However, in six of the cases examined post mortem a pituitary basophilic adenoma was found; in two other cases the pituitary body was described as normal, but as serial sections were not made this statement may not have been correct. Minor changes were found in some of the other ductless glands. Hence it would seem that the pituitary lesion was a primary factor in the syndrome. Secondary endocrine disturbances in the polyglandular syndrome, conceivably affecting the suprarenals, are suggested not only by the hypertension and the pigmentation but also by the terminal extreme weakness, by the glycosuria on the part of the pancreatic islets, and possibly by the osteoporosis on the part of the parathyroid glands.

This notable differentation by Cushing of pituitary basophilism will stimulate physicians and pathologists to study with fresh interest and larger grasp the instances that may come to notice of so-called polyglandular syndromes.

PEPSIN AND RENNIN

The ability of gastric juice to clot milk has been ascribed by Hammarsten to a special proteolytic enzyme, chymosin or rennin. The Pavlov school and others, however, have long maintained that there is no necessity of attributing rennet action to a special organic catalyst. This view was seemingly supported by the well known fact that practically all proteolytic enzymes, even those from vegetable sources such as papain from the melon tree, can effect the clotting of milk. In his last contribution to this subject, in 1923, Hammarsten concluded that there was no positive proof against identity of pepsin and rennin.

Recently Kleiner and Tauber[1] have reported the isolation, in comparatively pure form, of a rennin preparation from the mucosa of the fourth stomach of the calf. This preparation shows the highest clotting power yet reported; at the same time it is practically devoid of peptic activity. The elementary composition and the properties of the preparation indicate that it is a thioproteose. Unlike pepsin, it contains neither chlorine nor phosphorus. The authors state that it differs from pepsin in other ways. Rennin is irreversibly inactivated by alkali, it is easily soluble in dilute acid, it is not coagulated by heat, it gives quite different protein color tests, and it is not dialyzable. Moreover, its iso-electric point is p_H 5.4, while that of pepsin is 2.75, and it is soluble in water at its iso-electric point, whereas pepsin is not. In addition, the New York investigators have shown that the enzyme is present in the mucosa in the form of a precursor that becomes activated, as does pepsinogen, by hydrochloric acid. The zymogen differs from the active enzyme in that it is completely destroyed by contact with 50 per cent alcohol Efforts to obtain rennin in crystalline form, as has been accomplished for urease, pepsin, trypsin and amylase, are yet unsuccessful

[1] Tauber, Henry, and Kleiner, I. S.: Studies on Rennin: I. The Purification of Rennin and Its Separation from Pepsin, J. Biol. Chem. **96:** 745 (June) 1932; II. The Isolation of Prorennin, ibid. **96:** 755 (June) 1932.

The contribution here discussed marks a distinct advance in our knowledge of the chemistry of the digestive enzymes, a field opened by the discovery of the starch-splitting power of saliva by Leuchs a century ago

NO PLACE TO TURN!—BUT THE CHILDREN'S BUREAU!

According to a report by Genevieve Forbes Herrick in the Chicago *Tribune* and a subsequent editorial,[1] the federal Children's Bureau in the Department of Labor, now twenty years old, celebrated its birthday with a statement on the radio about its rapid growth and the services it is rendering to the people of the United States Miss Katharine F Lenroot, assistant to the chief of the bureau, told about a mother who inquired by letter whether it would be all right to feed her baby gunpowder to cure styes on the baby's eyes The mother was quite properly informed that gunpowder would be anything but harmless and certainly would not cure the baby's styes Miss Lenroot is credited with the statement that twenty years ago mothers troubled by questions of that kind would have had *no place to turn*

Leaving aside for the moment the essential stupidity of the question, one is caught immediately by that phrase "no place to turn" If that is correct, there must be something wrong with the memories of a great many people who have not grown so old that they are willing to be considered senile There are still some comparatively young people who seem to remember that there was once a genus, now said to be approaching extinction, known as the family physician The family doctor, according to this tradition, used to usher babies into the world, not infrequently having been in attendance at the births of their proud young parents some eighteen to twenty years before Then he used to take care of them in all their ills, real or imaginary, major or minor He often dashed out at night to reassure frightened young mothers, he was always willing to answer all kinds of anxious questions, he reminded parents about vaccinations and then proceeded to vaccinate the children He was quite a valuable institution in the community, if tradition is correct Apparently tradition is all wrong, however, because Miss Lenroot says that the parent of twenty years ago would have had to feed gunpowder to her baby with a fine experimental motive in order to ascertain whether or not it would cure the baby's styes She would have had no other place to turn!

But there is comfort! Others also have been deceived In a recent hearing on the work of the Children's Bureau, seven members of the Senate Committee on Commerce, including Senators Moses, Broussard, Stephens, Hawes, Bailey, Coolidge and Bingham, united in a minority report to the effect that they were not wholly convinced of the value of the child health activities of the bureau, and Senator Vandenberg added his own minority report opposing the extension or reviving of the so-called Sheppard-Towner Maternity and Infancy Hygiene Act These gentlemen put their signatures to the following statement: "It is significant that medical societies, including the American Medical Association, . oppose this legislation . This significance is all the more marked because it is known that the doctors who belong to these societies give more than half of their time to the poor, without price and without considering their time, . . . they go to the hospitals in their large cities and in their communities day after day, week after week and year after year, operating to save the lives of poor people without charging one single cent for their services"[2]

Perhaps our memory was right after all Possibly family doctors actually did exist as reputed No doubt they still exist notwithstanding the extraordinary efforts of certain philanthropists, sociologists, economists and governmental bureaucrats to abolish them Under all the hubbub, the tumult and the shouting about medical costs and the decadence of medical service, the family doctor still exists! Even if there were no federal bureaus, mothers wishing information about the health of their children would still have some place to turn.

Current Comment

ARTIFICIAL ANTIBODIES IN PLANTS

About twenty years ago, European bacteriologists expressed the hope that specific antitoxins and specific antiseptics might be produced by artificial immunization of plants A few preliminary tests were made by growing seedlings in soil moistened with diphtheria toxin Extractives of these immune seedlings, however, showed no demonstrable diphtheria antitoxin The general conclusion was drawn that plants probably cannot produce artificial specific defensive hormones That this conclusion may have been premature is indicated by Kostoff's[1] currently reported production of specific precipitins and specific proteolysins by a somewhat more elaborate botanic technic The Russian plant pathologist studied the acquired immunities between heterologous grafts and stocks with different species and genera of solanaceous plants Nicotiana tabacum, for example, was grafted onto Nicotiana glauca By the end of thirty-five days, the graft extracts contained a ++ antiglauca precipitin (ring test) The grafted stock (glauca), however, produced no demonstrable antitabacum precipitin but did develop an insusceptibility to the antiglauca precipitating hormone secreted by the graft Study of the interaction of the same plant extractives by means of dialyzation technics seemed to confirm these results and revealed that the antiglauca precipitin is accompanied by an antiglauca proteolysin. The complexities and intricacies of research in modern immunology open fascinating pathways to the investigator.

GALACTOSE

To most physicians the mention of galactose will serve merely to recall an apprenticeship in biochemistry during their student days. They are aware that this sugar rarely occurs free in nature but is readily built up in the mammary gland out of the dextrose of the blood into lactose. The latter is readily digested in the alimentary tract so as to yield dextrose and galactose, simple sugars that are in turn promptly absorbed. Galactose can then be converted into the physiologic carbohydrate glycogen and consequently serve the nutritive needs of the organism. Galactose occurs in the body also as an integral part of certain brain lipids. The assumption that galactose is poorly utilized has been corrected by Harding and van Nostrand[1] of Toronto, who have concluded, from experiments on man, that the conversion of galactose to dextrose can be much more rapid than has previously been supposed. More recent observations by Roe and Schwartzmann[2] at the George Washington University Medical School, in Washington, D. C., indicate that even in diabetic patients, who notably lack ability to metabolize dextrose in large measure without the assistance of adminstered insulin, galactose may nevertheless be utilized to an extent that is worth while. The blood galactose values obtained with diabetic patients after galactose ingestion were in all cases within the limits of the values obtained with normal persons on the same galactose intake. Perhaps the apparently good tolerance of diabetic patients for galactose is due to the fact that insulin may not be necessary for the anabolism of that sugar. Roe and Schwartzmann accordingly suggest that galactose might be made a valuable adjunct to the diet in the clinical management of diabetes mellitus. This is frankly contrary to the traditional views. However, the Washington biochemists venture to suggest that the use of a sugar having a nutritive value and satisfying sweetness, the administration of which by mouth produces practically no greater saccharemia in diabetic patients than in normal persons, might mark considerable advance in the control of diabetes and its undesirable consequences, such as diabetic retinitis and endarteritis, conditions alleged to be etiologically related to hyperglycemia. Galactose is also reported to have an excellent antiketogenic value.[3] Unfortunately, the cost of galactose is still too high to permit extensive practical tests of some of these suggestions. Usually, however, the industries find ways of overcoming such handicaps when prospects of new uses for their products beckon.

Association News

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Talks

The American Medical Association broadcasts on Monday and Wednesday from 10:45 to 10:50 a. m. over Station WBBM (770 kilocycles, or 389.4 meters). The Columbia chain program has been discontinued for the present.

The subjects for the week are as follows:

September 5. Holiday; no broadcast.
September 7. Cancer of the Larynx.

There is also a fifteen minute talk sponsored by the Association on Saturday morning from 10:45 to 11 over Station WBBM.

The subject for the week is as follows:

September 10. An Unneighborly Disease.

This schedule is based on Chicago daylight saving time, one hour faster than central standard time.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

CALIFORNIA

Personal.—Dr. John MacKenzie Brown, Los Angeles, has been appointed professor and head of the department of laryngology, rhinology and otology at the University of Southern California Medical School.——Dr. Sven R. Lokrantz, medical director, Los Angeles city schools, served as medical director of the Olympic Games.

Survey of Heart Disease.—The department of public health of San Francisco began a survey of heart disease morbidity, August 1, with the intention of continuing it for at least one year. Forms stressing etiologic diagnosis will be sent to physicians, hospitals and outpatient dispensaries in San Francisco. In a preliminary survey from March 15 to June 15, conducted by the heart committee of the San Francisco County Medical Society, only 800 cases were reported. Of the more than 1,500 physicians addressed, less than 10 per cent filed reports on cases of heart disease. Less than 50 per cent of the city's hospitals reported cases. A total of 6,500 forms was sent out in this preliminary survey. In March this year heart disease became reportable for the first time.

COLORADO

Licenses Revoked and Restored.—The state board of medical examiners adopted a resolution, July 11, revoking the license to practice medicine of Dr. William H. Vail, Denver. At this meeting the license of Dr. Kalmen C. Sapero, Denver, was restored.

CONNECTICUT

Personal.—Walter L. Simpson, for the past two years superintendent of Grace Hospital, New Haven, has resigned, effective August 1.——Dr. Theodore F. Foster, Knoxville, Tenn., has been appointed superintendent of health of West Hartford.——Dr. John Purney has been appointed medical examiner for New Britain.——Dr. Ross Granville Harrison, Sterling professor of biology, Yale University School of Medicine, New Haven, received the honorary degree of doctor of science from the University of Dublin, June 29.

FLORIDA

Society News.—Dr. Hermon Marshall Taylor, Jacksonville, read a paper on "Hygiene of Swimming" before the June meeting of the Duval County Medical Society in Jacksonville. ——The Orange County Medical Society was addressed, June 15, by Dr. Cyril J. Marshall, Orlando, on "Syphilitic, Tuberculous and Carcinomatous Skin Lesions."——Dr. Thomas F. Jackson, Dade City, was host to the Pasco-Hernando-Citrus County Medical Society at dinner recently.

Medical Society Sponsors Clinics.—The Orange County Medical Society recently adopted a plan for the operation of free clinics for the indigent in Orlando, scheduled to open September 1. A building has been donated by the county commissioners; water and lights are furnished by the Orlando utilities, and local welfare organizations will investigate patients and recommend them for treatment. According to the plan, there will be each week daily surgical clinics, three clinics for diagnosis, three for pediatrics, two for urology, three for diseases of the eye, ear, nose and throat, and two for obstetrics and gynecology. In addition, the Orange County Dental Association will conduct daily dental clinics. The physicians have agreed to discontinue all outside clinics for charity.

ILLINOIS

Society News.—Drs. George H. Ewell and Arnold S. Jackson, Madison, Wis., addressed the Schuyler County Medical Society, Rushville, September 1, on urologic problems and treatment of cholecystitis, respectively. Dr. Harold E. Marsh, Madison, conducted a clinic.——The Pike County Medical Society was addressed, July 28, by Drs. Harold Swanberg and Walter M. Whitaker, Quincy, on graduate study in Europe and practical electrocardiography, respectively.

Chicago

Facilities for Relief of Hay Fever.—The University of Illinois Research Hospital is conducting its second experiment with a special ward for hay fever patients. Special air filters free the air from pollen. Each week, from August 15 to October 1, a group of sufferers enters the ward for observation and tests, according to the plan. Only nights are spent in the hospital. Wesley Memorial Hospital has also announced the equipment of several rooms with air filters and rubber covered mattresses and pillows.

INDIANA

Dinner to Dr. Recher.—Friends from Brook, Kentland and Morocco honored Dr. Lawson H. Recher at a banquet, July 14, in recognition of his fifty years as a practicing physician in Morocco. A jeweled emblem and a fountain pen were presented to Dr. Recher.

Society News.—Dr. Thomas B. Noble, Jr., Indianapolis, addressed the Carroll County Medical Society, at Burrows, August 12, on "New Things in Surgery."——Dr. Harold A. Elkins, Mount Carmel, Ill., was the speaker before the Gibson County Medical Society, August 8, at Princeton, on "X-Rays of the Long Bones."——Dr. Thomas J. Beasley, Indianapolis, entertained members of the Hendricks County Medical Society at dinner at Indian Lake, near Indianapolis, August 5; Dr. Amos Carter, Indianapolis, recounted experiences of his fifty-four years of practice.

IOWA

Program of Linn County Medical Society.—Dr. Nathaniel G. Alcock, Iowa City, will address the Linn County Medical Society, Cedar Rapids, September 8, on one year's experience with transurethral prostatic resection; Dr. Robert A. Stewart will speak and conduct a clinic at Independence, September 29, on manic-depressive psychosis, dementia praecox, neurosyphilis and paranoia; Dr. Louis W. Sauer, Evanston, Ill., October 13, on feeding problems, including pyloric stenosis in infancy, anorexia in the larger child and malnutrition in the school child.

KANSAS

Licenses Revoked.—On June 21, the state board of registration in medicine revoked the licenses to practice medicine of the following for the reasons indicated: Dr. Clarence J. McKnight, Wichita, narcotic charge; Dr. Charles C. Keester, Wichita, conviction of manslaughter for which he is now serving sentence in the penitentiary, and Dr. David Gordon, Minneapolis, narcotic charge.

Society News.—Dr. John Albert Key, St. Louis, will address the Wyandotte County Medical Society, Kansas City, September 13, on "Arthritis, Experimental and Clinical." The Kansas City Southwest Clinical Society will meet with the county society in the morning at a clinical meeting on arthritis, when Dr. Key will hold a clinic at St. Margaret's Hospital.——Dr. Harry R. Wahl, Kansas City, addressed the Clay County Medical Society, June 29, in Clay Center, on "Recent Advances in Some Common Diseases."——The Franklin County Medical Society met, June 29, at Osawatomie, with addresses by Drs. Earle G. Brown, Topeka, and Richard L. Bower, Kansas City, Mo., among others, on undulant fever and the effects of sodium amytal on manic-depressive patients, respectively.

MARYLAND

Civic Groups Aid in Diphtheria Prevention.—For a number of years the Baltimore health department has assigned public health nurses to assist at the "baby days" of the Playground Athletic League during the summer and to cooperate with the Free Summer Excursion Society on the bay trips which it offers to about 1,300 parents and children each week. This year these civic organizations are cooperating with the health department in a campaign for the eradication of diphtheria. Toxoid inoculations are being made available for those who desire it at the "baby days" held in the schools and in the city parks and to families attending the excursions.

Health Department Retires from Robert Garrett Hospital.—An arrangement whereby the Baltimore health department has been conducting clinics for school and preschool children in the Robert Garrett Hospital was discontinued, September 1. Since this hospital was closed as a private institution eight years ago, Mrs. Henry Barton Jacobs has enabled the department to use a portion of the hospital for this purpose, carrying almost the entire expense for the service. Plans are being made for the transfer of the clinics for diseases of the eye and ear to the municipal building. It is hoped that the dental clinic will be removed to a neighborhood school. Plans for the tuberculosis, nose and throat and child welfare clinics had not been completed at the time of this report. During the eight years' existence of these clinics in the Robert Garrett Hospital, 83,550 children have been examined and treated. More than 500 children have been operated on annually for removal of tonsils and adenoids, and more than 3,000 have had refractions annually. The clinic services at the hospital were established through the efforts of Dr. Humphrey Warren Buckler, chief of the division of school hygiene, who began his uninterrupted service as a school physician to the city in 1906.

MASSACHUSETTS

License Restored.—At a special meeting of the board of registration in medicine, June 23, the license of Dr. John F. Cummings, Brockton, to practice medicine and surgery in Massachusetts was restored.

Personal.—Dr. Raymond A. Kinmonth, assistant superintendent of the Wrentham State School, has been appointed assistant to the commissioner in the department of mental diseases to succeed Dr. Charles Stanley Raymond, who has been appointed superintendent of the Wrentham school.——Dr. Michael Shaughnessy, Framingham, has been appointed medical examiner of the eighth Middlesex district to succeed Dr. James Glass.

Society News.—The Plymouth District Medical Society held its midsummer meeting at Plymouth, July 21. Speakers were: Drs. Herbert H. Howard, Boston, "Treatment of Ureteral Calculi"; Loring B. Packard, Brockton, "Present Status of Gastro-Intestinal Diagnosis by the Roentgen Ray"; Cadis Phipps, Boston, "Treatment of Pneumonia"; John S. Hodgson, Boston, "Treatment of Cerebral Tumors and Ventriculograms"; Timothy Leary, Boston, "Relation of the Medical Examiner to the General Practitioner."——Dr. Nels A. Nelson addressed the South End Medical Club, Boston, recently, on gonorrhea and syphilis.

MINNESOTA

Southern Minnesota Medical Meeting.—The annual meeting of the Southern Minnesota Medical Association will be held in Rochester, September 12. The morning will be devoted to clinics and demonstrations at the Mayo Clinic. Among speakers announced for the afternoon meeting are Drs. Horace Newhart, Minneapolis, on "Modern Methods of Caring for the Hard of Hearing"; Archibald H. Beard, Minneapolis, "Practical Diets in the Treatment of Diabetes"; Herbert W. Rathe, Waverly, Iowa, "Treatment of Congestive Heart Failure," and Theodore H. Sweetser, Minneapolis, "Pitfalls in the Diagnosis of Renal Tumors."

Chiropractor Sentenced.—George Sjoden, Kensington, a chiropractor, pleaded guilty, July 23, to practicing medicine without a license, before Judge Roeser at St. Cloud. He had agreed to cure a case of eczema for $20, the medicine to be obtained in Chicago, and had promised the patient immediate relief. Sjoden had been previously convicted of practicing medicine without a license. He is said to have admitted to the court that he had been arrested on two previous occasions for writing checks without sufficient funds, and to have been in other difficulties in Mora, Princeton and Motley. Sjoden claimed to be suffering from a severe case of asthma and stated that he would like to go to a different climate. Judge Roeser sentenced Sjoden to eight months in the Douglas County jail and gave him until August 2 to decide whether he would improve his health elsewhere. If he was still in Minnesota after that date he must serve his sentence.

MISSISSIPPI

Medical Fellowships.—The Mississippi State Board of Health, through the Rockefeller Foundation, has arranged for fellowships for one year's study for the following physicians, who will have choice of going to either Johns Hopkins University School of Medicine or Harvard University Medical School: Drs. James T. Googe, Meridian; George E. Riley, Jackson, and Archie L. Gray, Hazlehurst.

State Board News.—The Mississippi State Board of Health held its regular meeting, June 27-29. Medical examinations were conducted, June 28-29. Thirty-seven physicians were licensed to practice medicine, ten by reciprocity. At this meeting of the board, Dr. John W. Dugger, Jackson, director of the bureau of industrial hygiene and factory inspection for the past four years, was elected for another four-year term. Dr. Henry C. Ricks was selected to serve as director of the bureau of county health work. Dr. Ricks will succeed Dr. Calvin C. Applewhite, who has been transferred by the U. S. Public Health Service. The reduction in appropriation has made it necessary to discontinue the division of malaria control, and no appropriation was made to continue the activities of the bureau of communicable diseases.

MISSOURI

Society News.—The Buchanan County Medical Society was addressed, June 15, by Dr. James T. Stamey, St. Joseph, on "Some Uses of the Galvanic Current."——At the meeting of the Cass County Medical Society in Drexel, June 9, Drs. Otto J. Dixon and Joseph E. Welker, Kansas City, spoke on "Differential Diagnosis and Treatment of Intracranial Infection" and "Edema of Cardiac Origin," respectively.——Dr. Frederick B. Campbell, Kansas City, among others, lectured on proctology before the Clay County Medical Society, June 30, in Liberty.——Speakers before the Gasconade-Maries-Osage County Medical Society at Mount Sterling, June 23, were Drs. Richard S. Weiss, St. Louis, "Precancerous Dermatosis," and Louis H. Jorstad, St. Louis, "Cancer of the Lip and Mouth."——Allen O. Gruebbel, D.D.S., Lexington, among others, addressed the Lafayette County Medical Society in Odessa, June 28, on "Dental Hygiene and Diet."——At the June 24 meeting of the St. Francois-Iron-Madison County Medical Society, the speakers were Drs. Borden S. Veeder, St. Louis, "Some Common Conditions in Children and Their Treatment," and Warren R. Rainey, St. Louis, "Office Treatment of Rectal Conditions."——Drs. Herbert F. Van Orden and Elmer P. Monahan, Kansas City, addressed a joint meeting of the Johnson and Lafayette county medical societies, July 26, on "Rectal Complications of Pregnancy" and "Fungi of the Human Skin," respectively.

MONTANA

Society News.—Dr. Arlie R. Barnes, Rochester, Minn., addressed the Yellowstone Valley Medical Society, Billings, recently, on the treatment of cardiac disorders.——Dr. Albert D. Brewer, Bozeman, was elected president of the Montana Public Health Association, July 12, at its annual meeting in Miles City.

NEW YORK

State Sanitary Code Revised.—Extensive changes in the state sanitary code have been announced by the Public Health Council. Psittacosis and Rocky Mountain spotted fever have been added to the list of reportable diseases, and mumps, puerperal fever and trachoma have been removed. The period of detention for dogs suspected of being rabid has been reduced from three weeks to one week. Local health officers must now report carriers of typhoid and paratyphoid fever. The new code also provides that cases of chancroid, gonorrhea and syphilis may be reported by an identifying number or symbol, provided the physician keeps a record of the symbol; names must be reported, however, of persons who discontinue treatment while in the infective stages. Another new requirement is to the effect that eating places must inform customers whether raw or pasteurized milk is being served. In the section relating to swimming pools, regulations have been added requiring that foot baths containing fungicidal solutions be provided.

New York City

Gifts to Hospital.—New York Post-Graduate Medical School and Hospital announces the receipt of a number of gifts during July, as follows: $1,000 from the Josiah Macy, Jr., Foundation, for study of cholesterol metabolism in relation to arteriosclerosis; $2,000 toward current expenses, anonymously given; $7,500 from Mr. Allen Wardwell and $2,000 from the legacy of Mrs. Roger B. Williams toward expenses of the Reconstruction Unit. Final payment of a legacy totaling $25,000 from the will of Julia Seligman has also been made and the money used for research and philanthropic purposes in the eye clinic.

Personal.—Dr. Charles Gordon Heyd, president of the Medical Society of the State of New York, has been given the Legion of Honor Award while on a visit to France, it is reported. Dr. Heyd served during the World War in the French Surgical Corps and later was transferred to the United States Army. He is a native of Canada but has lived in the United States twenty-seven years.——Henry Fairfield Osborn, Sc.D., president of the American Museum of Natural History for nearly twenty-five years, celebrated his seventy-fifth birthday, August 8. He will retire from the presidency of the museum at the end of this year to devote himself to finishing a work on elephantine mastodons and other writing.

Graduate Courses in Neuropsychiatry.—Beginning October 3, Columbia University College of Physicians and Surgeons will offer graduate courses in neurology and psychiatry, designed for graduate medical students. The courses, which are aimed to cover, in part, the sociological and educational fields, are so arranged as to meet the desire of applicants feeling the need of further knowledge in these branches. During the first ten weeks of the academic year, beginning October 3 and ending December 10, there will be two series of courses, one devoted principally to psychiatry (trimester in psychiatry) and one devoted principally to neurology (trimester in neurology). Any individual course in either trimester, except clinical assignments in neurology and psychiatry, may be taken singly. Sixteen weeks, beginning January 23, 1933, and ending May 13, 1933 (semester in neuropathology), will be devoted entirely to intensive work in neuropathology. The executive officer is Dr. Howard W. Potter, 722 West One Hundred and Sixty-Eighth Street, New York.

Fraudulent Food Inspectors.—The health department issued a warning to food dealers, August 6, against unauthorized inspectors who present flashy "gold" badges as credentials. The official inspector carries an identification card bearing his photograph, his signature and the number of his badge. Dealers were warned to demand that any person claiming to represent the health department produce this card and, further, that police should be called when only a badge inscribed "Health Service City of New York" or other fake credentials were presented. It is reported that the fraudulent inspectors are hired by "health service" concerns which advertise for men to solicit food handlers' cards. When a man accepts a position as solicitor he is met as he leaves the building by a stranger, who tells him he will require a badge, which is then offered to him for $3. "Regular food inspectors of the department of health do not solicit," the health commissioner pointed out. "Food handlers are advised by them to go to the occupational clinic of the department of health or to their own physicians for examination for the health cards which every food handler must have."

OHIO

Activities of State Medical Board.—Dr. James M. Gorslene, Cleveland, was deprived of his certificate to practice in Ohio for six months after a hearing by the state medical board on a charge of unprofessional conduct. Dr. Gorslene has appealed to the Common Pleas Court. Among other items of business transacted by the board at its meeting, July 11-12, in Columbus, the certificate of Paul H. Strand, Youngstown chiropractor, was suspended for three months for advertising. Two hundred and eighty licenses to practice medicine and surgery were granted at this session.

Society News.—Drs. David A. Tucker, Jr., and Harold F. Downing, Cincinnati, addressed the Clinton County Medical Society at its June meeting on "Effects of Prolonged Use of Insulin" and "Early Diagnosis and Treatment of Acute Poliomyelitis," respectively.——Drs. Robert and Ralph G. Carothers, Cincinnati, discussed fractures at a meeting of the Greene County Medical Society, Xenia, July 7.——Dr. Nathan Worth Brown, Toledo, addressed the Wood County Medical Society in June on "Abdominal Symptoms in Cardiac Disease and the Relation of Acute Indigestion to Heart Disease."——At a meeting of the Geauga County Medical Society, Chardon, June 29, Dr. Scott C. Runnels, Cleveland, made an address on "The Facts of Maternal Mortality."——Dr. Charles H. Creed, Athens, addressed the Fairfield County Medical Society, Stoutsville, June 14, on brain tumor.——The Doctors Symphony Orchestra of Akron gave the thirty-eighth and final concert of the season, June 12, at Springfield Lake Sanitarium. The orchestra now has thirty-nine members.——Radiologists of Cincinnati have recently organized a radiologic section of the Cincinnati Academy of Medicine. Officers elected are Drs. Sidney Lange, president, and Harold G. Reineke, secretary. This section will furnish a program each year.

OREGON

Personal.—Dr. Seth M. Kerron, Eugene, health officer of the city and of Lane County for fifteen years, resigned, July 2. ——Dr. Joseph Myers, health officer of Albany since 1918, resigned, July 13. He is 93 years old.

Hospital News.—The new state tuberculosis hospital at Salem was formally opened to the public recently. The fireproof structure, which will accommodate ninety patients, cost $95,000, including equipment. Dr. Grover C. Bellinger is the superintendent.

PENNSYLVANIA

Personal.—The Lycoming County Medical Society at its annual picnic at Williamsport, August 12, observed the seventy-fifth birthday of Dr. Joseph W. Albright, Muncy, by presenting to him an album containing the names of the members of the society.

Philadelphia

Poliomyelitis Delays Opening of Schools.—Philadelphia public schools will not open the first week of September, as scheduled, because of an epidemic of infantile paralysis in the city, it was announced August 29. Twenty-nine new cases were reported over the week-end, bringing the total for the year to 331, according to newspaper accounts. In 1916, when a severe epidemic occurred, 387 cases were reported for the corresponding period. There have been twenty-seven deaths since January 1. Two weeks ago a corps of more than 100 physicians was assembled by Dr. J. Norman Henry, director of public health, to act as consultants in districts coinciding with their own neighborhoods if the disease should assume epidemic proportions. It was predicted that schools might not open before October 1. The Philadelphia County Medical Society at the request of the health department has asked all physicians who have or have had cases of infantile paralysis to send their names and addresses to the society in order that serum may be obtained from them for treatment in subsequent cases. Physicians are urged to report all suspicious cases promptly to the health department and diagnosticians will be sent at once if required.

SOUTH DAKOTA

Society News.—Dr. Philip F. Donohue, St. Paul, addressed the Twelfth District Medical Society, July 29, at Wilmot, on "Transurethral Prostatectomy."——Drs. John H. Moore and Edwin B. Banister, Grand Forks, N. D., addressed the Watertown District Medical Society, August 9, on "Alleviation of Pain in Obstetrics" and "Sinusitis in Children," respectively.

UTAH

Hospital News.—The new U. S. Veterans' Hospital at Salt Lake City, with a capacity of 103 beds, was placed in operation early in July with Dr. Horatio D. Luse as chief medical officer. Dedication ceremonies were held, July 24.

Personal.—Dr. Frank M. McHugh, Salt Lake City, president-elect of the Utah State Medical Association, and Dr. Lyman L. Daines, dean of the University of Utah School of Medicine, were recently appointed members of the Salt Lake City board of health.

WASHINGTON

State Medical Meeting at Tacoma.—The annual session of the Washington State Medical Association, which will be held in Tacoma, September 12-14, is to be devoted principally to the economics of medicine. Guest speakers will be Dr. Ray Lyman Wilbur, Washington, D. C., Secretary of the Interior and chairman of the Committee on the Costs of Medical Care, who will speak at the opening general session; Nathan Sinai, Ph.D., Ann Arbor, Mich., who will speak on "The Health Problem of the Industrial Worker" and on "Health Insurance"; Dr. Rosco G. Leland, director, Bureau of Medical Economics, American Medical Association, Chicago, on "Current Trends in Medical Practice" and "Economics of Medicine"; Mr. Frank P. Foisie, Seattle, on "A Layman's Attitude on Medical Care of Injured Workmen" and Harry Ellsworth Foster, Olympia, assistant attorney general, "Some of the Legal Aspects of Reorganized Medicine." In addition, there will be reports on "Legislative Proposals Relative to the Medical Aid Law," "Present Status of Health Insurance in the State of Washington," and "Medical Care of Veterans and Government Employees." Dr. Joseph A. Pettit, Portland, will address the opening meeting on the work of the American Medical Association. Dr. Wilbur and Dr. Leland will address a public health meeting, Monday evening, September 12, under the auspices of the Public Health League of Washington, which will hold its annual meeting during the week. A scientific exhibit is being arranged by Drs. Conrad Jacobson, Seattle, and Treacy H. Duerfeldt, Tacoma. The annual dinner and dance will be given Tuesday evening at the Hotel Winthrop, and the Washington State Medical Golf Association is to have its tournament on Monday, September 12, at the Tacoma Country and Golf Club.

GENERAL

Honorary Members Elected.—The American Society of Clinical Pathologists announces the election to honorary membership of the following: Dr. Charles Achard, professor of clinical medicine, Faculty of Medicine, Paris; Dr. Edward C. Dodds, Courtauld professor of biochemistry, University of London, and Col. Charles F. Craig, director of the department of tropical medicine, Tulane University School of Medicine, New Orleans.

Spotted Fever in the East.—Fifteen cases of the eastern type of Rocky Mountain spotted fever are reported to have occurred within recent weeks in Maryland and five in Washington, D. C. Two Washington children died of the disease. In addition, the Maryland state department of health was said to be investigating fourteen cases reported as typhus fever but suspected of being spotted fever. Citizens of that area have been warned to exercise care when in the country to avoid woods and bushes that might harbor ticks. Vaccine against Rocky Mountain spotted fever, which was identified in the East only two years ago, is made only at the laboratory of the U. S. Public Health Service in Hamilton, Mont.

Cancer Films.—In the interest of medical education, the *American Journal of Cancer* is offering, without cost, a series of motion picture films on cancer for showing before medical groups. The films now ready for distribution are "Cancer of the Skin," based on material gathered by Drs. Joseph Colt Bloodgood and Charles F. Geschickter of Johns Hopkins University School of Medicine, and one showing "Technical Methods of Cancer Research," taken at the Institute of Cancer Research, Columbia University. The films are obtainable in either 16 or 35 mm. widths and are adequately titled so that no explanation is required while they are being shown. They are available for use in the United States only. Further information may be had from the Motion Picture Department, *American Journal of Cancer*, 1145 Amsterdam Avenue, New York.

Journal Transferred to Society of Parasitologists.—Henry B. Ward, D.Sc., professor and head of the department of zoology, University of Illinois, Urbana, owner and editor for eighteen years of the *Journal of Parasitology*, has given the journal to the American Society of Parasitologists. It now becomes the official organ of the society and the September issue will be the first under its auspices. An editorial committee will manage and edit the journal, assisted by a rotating editorial board representing the various divisions of parasitology. William W. Cort, Ph.D., professor of helminthology, Johns Hopkins University, School of Hygiene and Public Health, Baltimore, is chairman of the committee, and the other members are Robert W. Hegner, Ph.D., and Francis M. Root, professor of protozoology and associate professor of medical entomology, respectively, Johns Hopkins University, School of Hygiene and Public Health, Baltimore.

Health Conditions in 1932.—Inquiries made to public health officers throughout the country by the U. S. Public Health Service recently have revealed that the state of the public health is generally favorable. Mortality rates and prevalence of reportable diseases are said to be definitely less for the first six months of 1932 than for the same period in 1931. The infant mortality rate for eighty-two cities was 53.3 for that period as compared with 58.9 for 1931. It was pointed out, however, that the conditions which might be expected to increase under economic stress, such as malnutrition, are not reportable. In answer to a questionnaire sent to state health officers and a number of city and county officials, 88 per cent of the 94 who expressed an opinion said they believed the nonreportable diseases showed no appreciable change from 1930 or were less prevalent. More malnutrition and underweight and more demand for free hospital and clinic service were reported in some areas.

Warning Against Swindler.—A man giving the name M. R. James is reported to have swindled a number of physicians in Georgia by posing as a representative of the "Washington Instrument Company," of Washington, D. C. According to the report, this man offers standard medical and surgical equipment at greatly reduced prices, collects a payment, and cashes checks made out to the Washington Instrument Company before leaving a town. He is described as being about 35 years old, 5 feet 8 or 10 inches tall, with blue eyes and brown hair, and appears to be conversant with the business. It is suggested that physicians may protect themselves by refusing to give payments to any representatives or to make out checks to them individually. The Bureau of Investigation of the American Medical Association has no record of M. R. James or of the Washington Instrument Company. Telegrams addressed to the firm were returned with a notation that there was no such firm in Washington.

Fraudulent Salesman for Medicinal Liquor.—A Michigan physician has reported an impostor who claims to sell medicinal liquor and alcohol under a government permit as a representative of the "Ukiah Grape Products Company, 40th floor, Chanin Building, New York City." The physician gave an order and a check to the alleged salesman, who declined to have the usual official papers made out, saying that his firm saved the customer that trouble. When the victim did not receive his order, he wrote to the firm, but his letter came back marked "Removed—left no address." The Bureau of Investigation of the American Medical Association has no record of a firm of this exact name but does have a newspaper reference, dated 1924, to the "Ukiah Products Company" of New York, the manager of which was arrested for what was said to be a nation-wide plot for the distribution of high proof wine and for the alleged distribution of a so-called tonic, of 18 per cent alcoholic strength. It is not known whether the two firms have any connection.

Impostor Identified.—An account of the activities of an impostor in Bristol, Tenn., published in The Journal, August 6, page 484, brought to the American Medical Association a letter from a California physician enclosing the criminal record of a man whose methods closely resembled those of the man described in the Tennessee report. This record, taken from the annual report of the California State Board of Medical Examiners, contained a picture of a man who is variously known as George Stanley Paris, George I. Paris, George Samuel Isaacman and Samuel Paris. It was sent to Bristol, where the subject was identified as the same person who posed as "Dr. Wilson" there a few weeks ago and applied for admission to the staff of the local hospital. Meanwhile another report has come from Brooklyn, indicating that the same man has appeared there. Giving the name George S. Paris, he applied for membership on the courtesy staff of St. Catherine's Hospital, after which he cashed two checks for $10 each. Both were returned marked "no account." On his application blank at St. Catherine's, Paris gave two fictitious New York addresses and said that he was a graduate of Leland Stanford University. In addition, he claimed that he had served an internship at Cedars of Lebanon Hospital, Hollywood, and Hollywood Clara Barton Memorial Hospital, that he had been licensed in California and had a temporary license in New York, and that he was a member of the Los Angeles County Medical Society and of the American Medical Association. The California state board discloses that in 1931 a George S. Paris, while serving an "internship" at the Windsor Hospital, Glendale, Calif. (not an accredited hospital), applied for a position as ship's surgeon on a transpacific liner, stating that he was a graduate of the University of Illinois and that he held a California license by reciprocity. No record can be found to show that this person has ever even attended a medical school or received a license to practice. Records of the California Bureau of Criminal Identification and Investigation show that Paris has served several prison sentences in California and Missouri. The report of the California board indicated that at the time it was issued he was confined in the United States Disciplinary Barracks, Alcatraz, Calif., from which he was to be released, Jan. 15, 1932. The California records describe Paris as 5 feet 6½ inches tall, about 22 years old in 1931, with black hair and gray eyes.

CANADA

Hospital News. — The Toronto Orthopedic Hospital has been merged with the Toronto East General Hospital.——The cornerstone of a new surgical building for the Toronto Hospital for Consumptives at Weston was laid, June 1, by the mayor of Toronto.

Summer Clinics.—The annual "Summer School Clinics" sponsored by the Vancouver Medical Association will be held, September 13-16. Lecturers will be Drs. Louis H. Clerf, Philadelphia, who will lecture on various phases of otolaryngology; Leo Eloesser, San Francisco, on diseases of the lungs; George C. Hale, London, Ont., on heart disease and nephritis; William E. Gallie, Toronto, on fractures, birth injuries and sympathectomy; William B. Hendry, Toronto, on problems of pregnancy; Henry F. Helmholz, Rochester, Minn., on thyroid disorders and acute abdominal conditions in childhood and pyelitis; Frederick R. Miller, London, Ont., on functional neurology and myology, and Karl F. Meyer, Ph.D., San Francisco, on biologic products in daily practice, food poisoning, poliomyelitis and animal-borne infections. Dr. Thomas C. Routley, Toronto, secretary, Canadian Medical Association, will address a luncheon meeting, September 13. Clinics will be held in Vancouver hospitals three afternoons and a golf tournament on Thursday.

FOREIGN

Funds for Research.—About £120,000 has recently been made available to several English institutions for research in cancer and tuberculosis. The Royal College of Physicians of London will have £15,000 for work on tuberculosis and Westminster Hospital, £5,000. The Royal College of Surgeons of England will receive £10,000 and the Radium Institute £5,000 for cancer research, according to the *Lancet*.

Personal.—The Jacksonian Prize for 1931 has been awarded by the Royal College of Surgeons of England to J. Paterson Ross of St. Bartholomew's Hospital for an essay on surgery of the sympathetic nervous system.——A portrait of Sir W. Ashley Mackintosh, emeritus professor of medicine at Aberdeen University, Aberdeen, Scotland, was recently presented to the university as a testimonial from his friends and former students. A replica was presented to Sir Ashley and a fund of £1,000 remaining from the project will be used at Sir Ashley's request for the aid of students in time of sickness.

Graduate Course in Pediatrics.—The Faculty of Medicine of the University of Strasbourg announces a course in pediatrics to be given at the Children's Clinic, October 10-22, under the direction of Professor Rohmer. A variety of subjects will be covered, including nutrition and feeding of infants and older children, digestive disturbances, infectious diseases, disorders of the nervous system, tuberculosis and hereditary syphilis and social aspects of child health. For information address Professor Rohmer, director, Children's Clinic, Hôpital Civil, Strasbourg, France.

Stolp Prize Competition.—The biennial scientific competition of the Janus Stolp Foundation of the University of Leiden has been announced. The subject chosen is "An Original Contribution on the Psychology of the Knowledge of Space in the Blind." It is desired that the essayists should make a general résumé and critical review. Manuscripts, which must not exceed 40,000 words, are to be sent to Prof. W. B. Kristensen, 31, Witte Singel, Leiden, before Jan. 1, 1934. They may be in Dutch, German, English, French and Latin and must be typewritten, signed with a motto and accompanied by a sealed envelop with the same motto enclosing the name and address of the writer. The winner will receive a gold medal of the value of 250 florins and 250 florins in money, or if he prefers, the whole sum in money.

Government Services

Change of Station in the Navy

Lieut. Thomas M. Arnett from naval hospital, Washington, D. C., to marine barracks, Quantico, Va.; Lieut. Ralph M. McComas from naval hospital, Boston, to naval training station, Newport, R. I.; Lieut. Comdr. Robert H. Collins from U. S. S. *Saratoga* to naval dispensary, naval air station, Sunnyvale, Calif.; Lieut. Robert A. Cooper from navy yard, Boston, to the Asiatic Station; Lieut. Howard K. Sessions from naval hospital, New York, to naval air station, Lakehurst, N. J.; Lieut. Herbert G. Shepler from naval training station, Newport, R. I., to the Asiatic Station.

Cancer Research

The ninth annual report of the British Empire Cancer Campaign points out the trend toward a biologic view of the nature of cancer—the gene nutation theory. The work on cancer antiserum has excited considerable interest. Dr. Lumsden and his co-workers have succeeded in separating the euglobulin fraction of an anticancer serum from sheep ten times more effective in destroying cancer cells than the serum from which it is derived. Injections into implanted mouse tumors produced destruction of the tumor and absorption of the cells, and cancer immunity followed (autovaccination). Similar treatment of spontaneous tumors seems promising. Undestroyed portions of the tumor were removed and implanted elsewhere. If the autoplasts failed to grow the mouse became resistant, so that cancer cells were both prevented from growing and were destroyed. In a control group treated with normal sheep serum the tumors were not affected. Dr. Lumsden states that two curative processes follow the treatment. Local destruction of tumor cells occurs when the concentration of euglobulin is sufficiently high. This reaction is rapid and soon ceases to be effective, but by a mechanism of autovaccination it immunizes the mouse against cancer, and its tissues acquire an increased resistance, which completes the local cure and prevents recurrence. However, Dr. Lumsden is not yet prepared to recommend the treatment for human beings and earnestly begs that no requests be made for serum for this purpose.

CANCER-PRODUCING SUBSTANCES

Dibenzanthracene has proved a potent cancer-producing substance. Dissolved in fats, it produces connective tissue tumors and sarcomas in mice and rats. The tumors can be passed on by grafting into other mice and rats and have now reached as many as thirty-seven generations. Mustard gas seems to retard the production of cancer by these and other carcinogenic agents. Further work on tobacco tars shows that smoking plays little or no direct part in the production of cancer.

TREATMENT

Observations extending over three or more years in a considerable number of cases treated by radium (cervix, breast, tongue, pharynx and rectum) allow an estimate of the percentage of cures. This is rather disappointing, though there are encouraging signs of improvement with increasing refinements in the methods of applying radium. With better methods of filtration, cases of late radium reaction are becoming less frequent. In cancer of the rectum, striking differences are found in the survival rate after operation according to the parts affected. When limited to the rectal wall, excision completely eradicates the disease; when there is extrarectal spread but no gland metastases, a good prognosis is justified; with gland metastases, surgery is disappointing. The percentages of patients alive after years in these three groups were, respectively, 80, 73 and 7.

Preservation of Food by Carbon Dioxide

Experiments carried out by the government low temperature research station at Cambridge and the fish research station at Aberdeen promise to open up a new area in the preservation of food. Solid carbon dioxide has been extensively used as a refrigerant in trades such as the ice cream industry and in the transport of fish and other perishable foodstuffs. But its potentialities in preservation, apart from the refrigeration of food, now seem to be much more important. It has been proved that carcasses or fish can be kept fresh for long periods in an atmosphere rendered inert by carbon dioxide and maintained at a low temperature. The meat keeps in perfect condition, as if freshly killed, and suffers none of the deterioration caused by chilling or refrigeration. The cool carbon dioxide inhibits bacterial deterioration. By means of this method it should be possible to import fresh meat from Argentina and Australia. The potentialities in the supply of fish are even greater. At present fish from as far as the Greenland banks has to be packed in ice and quickly disposed of on landing. Trawlers fitted with carbon dioxide apparatus could bring back fish fresh as when caught from the farthest arctic fishing grounds or even from below the equator, where the seas have never been fished despite their richness in fish life, owing to the impossibility of bringing back the catch in a fresh state.

Low Mortality Record for Tuberculosis

In harmony with the continuous fall in the mortality from tuberculosis in Great Britain over nearly a century, the figures for the year 1930 are the lowest on record:

	England and Wales	Scotland
Total number of deaths from tuberculosis:		
All forms	35,745	4,286
Pulmonary	29,414	3,024
Death rates from tuberculosis per 100,000 population:		
All forms: Males	103.7	95
Females	77.0	82
Pulmonary: Males	86.3	68
Females	62.4	58

All ages and both sexes share in the decline, which is more marked in childhood and less in young adult life and old age.

INCREASE OF TUBERCULOSIS IN YOUNG WOMEN

But there is a curious exception to the general decline of tuberculosis. At the eighteenth annual conference of the National Association for the Prevention of Tuberculosis, Dr. N. D. Bardswell, principal assistant medical officer of the London county council public health department, stated that there was an increase in the mortality from pulmonary tuberculosis in young women at ages 15 to 25, which was practically limited to the unmarried. The increase dated from 1901, the period of the emancipation of women, when a profound change took place in their social habits on their entry into a wage-earning life. He attributed the increase to (1) fatigue consequent on their employment and long journeys to and from home in overcrowded trains and busses, (2) want of rest and late hours to bed following amusements after a long day's work, (3) neglected colds, and (4) unsatisfactory meals, such as "the tea and bun lunch." Clerks, typists and shop assistants were as prone to break down with pulmonary tuberculosis as young factory workers, machinists and others engaged in poorly paid trades. That the young married women did not break down like the unmarried worker of the same age he attributed to the advantage of removal from the ranks of wage earners.

Spahlinger's Vaccines

The reticence of Spahlinger in spite of his claim that he has disclosed his secrets has already been mentioned in The Journal (April 23, p. 1487; and July 2, p. 46). He has recently submitted a statement to the government, and it has been sent to various scientific authorities. They all draw attention to the general character of the statement and the absence of the necessary details of bacteriologic technic. They regard the information as insufficient for the preparation of vaccines identical with his. They note that the statement does not relate to the preparation of the curative serum used by him for the treatment of tuberculosis in man. The medical research council and the majority of the other authorities consulted consider that if a sufficient quantity of bovine vaccine can be supplied by Spahlinger the question of experimental trial on animals might be considered. But detailed information as to dosage, methods of administration and standardization would be required. They consider that a clinical investigation of the immunizing value of the human vaccine in human beings would be undesirable. The ministry of agriculture is in communication with Spahlinger concerning an experimental trial of the bovine vaccine on animals, and details of the method of preparing and administering bovine vaccine. Spahlinger has undertaken to supply a sufficient quantity of the bovine vaccine as soon as it can be prepared.

Lord Moynihan's Presidency of the Royal College of Surgeons

After holding the office of president of the Royal College of Surgeons for six years, Lord Moynihan has been succeeded by Sir Holburt Waring. His tenure of the leading position in the British surgical world has been distinguished in several ways. He was the first provincial surgeon to be elected and he has held the office for an unprecedented period, twice as long as any of his predecessors. But it is the great reforms made during his presidency that render it memorable. Before his time the college was regarded by many people as an examining body with an admirable museum, in connection with which important lectures were delivered. Under his lead extensive provision has been made for experimental research. He has never been tired of preaching that to the great detriment of surgery, laboratory experiments are carried on regardless of its problems and mainly for the advance of physiology. Now a new suite of laboratories has been added to the college. Still more important, the Buxton Browne research farm has been established at Downe in Kent, near the former home of Charles Darwin. Lord Moynihan has also collected large sums for research and the endowment of scholarships, which carry the stipulation that the holders shall continue to work in the hospitals. Thus his ideal that hospital work, museum work and laboratory work should be brought into conjunction has been achieved. Lord Moynihan is now looking forward to spending more time in his northern home and returning to his practice in Leeds, where he made his reputation as a surgeon.

The Voluntary Sterilization of Defectives

The sterilization of mental defectives continues to be a subject of controversy. In a joint letter to the *Times*, a number of leading physicians, who are members of the Eugenics Society, state that there are good reasons for supposing that mental deficiency is increasing. Of the estimated 300,000 mental defectives in England and Wales, only a small proportion are confined in institutions and it is not feasible or even desirable to segregate more than a third of the total. It is generally agreed that no mental defective should have children, irrespective of whether the defectiveness results from hereditary or from environmental influences. The Eugenic Society has never advocated sterilization except as an auxiliary to segregation. The proposals, made from time to time in favor of sterilization as an economical substitute for segregation, have never received the support of the society, and the members of the society do not regard it as probable that the legalizing of a voluntary and carefully safeguarded measure of sterilization would be followed relaxation of the efforts now being made to extend existing institutional provision. But they believe that the legalizing of voluntary sterilization will be welcomed by local authorities as a valuable accessory means for dealing with an otherwise discouraging problem. It would do much to disseminate the eugenic conscience which would be necessary for tackling the larger problem of sterilizing subnormal carriers of defect. These carriers can often be detected, particularly if they have already given birth to defective children. Many of them belong to a recognizable low grade, though not certifiable. The society therefore recommends the legalizing with safeguards of voluntary sterilization, accompanied by the educative influences of the Central Association for Mental Welfare and other organizations.

Meeting of the French Assembly of General Medicine

The Association française de médecine générale, the creation of which was announced in these letters, held recently its first meeting in Paris, at the Hôpital de l'Hôtel-Dieu, under the chairmanship of Professor Carnot, with the attendance of a large number of delegates from Paris and the provinces, including Professor Stassen of Brussels. The discussions centered about rural tuberculosis, the rôle of heredity and of contagion in tuberculosis, the age at which contagion commonly occurs, and the best methods of prophylaxis. Following the presentation of the communications, Professor Carnot, Dr. Jules Renaut and Dr. Lesné summarized the opinions uttered, comparing them with the usually accepted theories, in order to arrive at conclusions; for that was the original purpose of the new association—namely, the comparison of documents coming from the general practitioners in all points of France. The conclusions reached were drawn up in the following form: Rural tuberculosis is frequent. In its transmission, heredity and contagion play a big part. It is impossible clinically to establish the relative importance of each, but from a practical point of view there are tuberculous families; the descendants are weakly and easily become victims of the disease. Contagion, which is chiefly to be feared, develops in an hereditary or an acquired terrain. Contagion may occur at any age. It does not spare the child, the adult or the aged; but the child is more susceptible to contagion. The disease is prevalent within the family in the most salubrious regions—in the isolated cottages of the mountains as well as in the plains. The person responsible may be spreading the disease by coughing; he often left the village for the city in good health and returned sick to his native heath. The rôle of contagion thus imported has been considerable in recent years. Ex-service men who contracted tuberculosis in the army and were invalided home or were discharged have been frequent sources of infection in the rural districts.

Among the many conditions that are regarded as conducive to the appearance of tuberculosis, there are in the rural districts the same causes of organic deficiency that are found in the cities: overwork, late hours, dissipation commonly associated with alcoholism (so frequently encountered in poor tenements), poverty and insufficient or defective alimentation. The solution of the problem is complex. Vaccination alone will solve it some day. It is too early to make vaccination compulsory, but it is already recommended by many physicians in contaminated environments. Compulsory notification, which is desired in many quarters, is not feasible at present; it has, however, been proposed for the local dispensary, an auxiliary organism of the attending physician, a center of equipment and of social preservation. Such preservation would be greatly favored by antituberculosis instruction, which should begin in school and should be continued afterward, in both village and city. All physicians protest against the inadequate nature of the means of isolation. The sanatorium, it is held by some, has outlived its usefulness. The departmental *sanatorium-hospital* is unanimously demanded. Convinced of the importance of contagion, the physician considers the isolation of the spreader of tubercle bacilli indispensable. The second Sessions des assises médicales will consider the topic "Cancer Houses," under the chairmanship of Professor Castaigne.

The French Congress of Medicine

The twenty-second session of the Congrès de médecine de langue française will be held in Paris, Oct. 10-12, 1932, under the chairmanship of Prof. Fernand Bezançon, with the president of the republic in attendance. The detailed program has been published in order to make an appeal for articles written by the clinicians of France and foreign countries. Three important questions have been placed on the program: On the first topic, "Lymphogranulomatosis," the following papers will be presented: Anatomoclinical forms of malignant lymphogranulomatosis. Speakers: Mr. Maurice Fabre of Lyons: Anatomoclinical Characters of Malignant Granulomatosis; Its Abnormal Types; Messieurs Huys of Brussels and Gibert of Geneva: Radiotherapy in Malignant Lymphogranulomatosis; Messieurs Weissmann-Netter, J. Delarue and V. Oumansky of Paris: The Results of Experimentation in Malignant Lymphogranulomatosis. The second topic on the program will be "Acrocyanoses." Messieurs Villaret, Justin Bezançon and Cachera will consider "The Physiology and Pathology of Peripheral Vascular Disorders; Messieurs May and Layani will present a clinical study on "Essential Acrocyanosis." The third question on the program will be "Medicosurgical Treatment of Pulmonary Abscesses." Messieurs E. Sergent and Kourilsky, with the surgical collaboration of Messieurs Baumgartner and Iselin, will consider "The Therapeutic, Medical and Surgical Indications in Pulmonary Abscesses." Mr. G. Lardennois will study the operative technic. Messieurs Kindberg and Soulas will speak on "The Bronchoscopic Methods in Pulmonary Suppurations." Mr. Etienne Bernard will discuss "The Action of Emetine in the Treatment of Pulmonary Abscesses." Announcement of further communications on the various subjects should be made to the General Secretary, Professor Abrami, 9 Rue de Lille, Paris.

BERLIN

(From Our Regular Correspondent)

Aug. 1, 1932.

Is Unemployment Undermining the Public Health?

"Unemployment in Germany is affecting to a terrible extent the nutritional condition of the poorer classes. A large number of insured persons and their children who are quartered in sanatoriums and homes for convalescents are found, on admission, to be in a physical condition corresponding to the worst postwar years." It was Dr. Frommhold, the president of the Landesversicherungsanstalt Hannover, who uttered these alarming words. On inquiry of several *landesversicherungsanstalten*, the federal public health service, the sociohygienic institutes and many physicians, it was found that these observations reflect the conditions in at least certain portions of the country. The physicians of some children's sanatoriums and homes for convalescents (particularly in central Germany) report that many children who are admitted to the homes hardly know what it means to have an adequate warm meal. It often happens that at first they cannot retain the nourishing warm food prepared under medical supervision. Sometimes two weeks elapse before these young patients can get accustomed to a normal diet with adequate warm meals. Furthermore, many women and girls are again found to be suffering from serious anemia, a disease that, during recent years, appeared to have been eradicated. These anemic patients, for the most part, had not had proper warm meals.

Likewise from tuberculosis sanatoriums information is furnished that the patients—including men and women—are often weak for lack of food, when admitted, and that it takes about two weeks to get them into a somewhat normal condition of nutrition.

In Berlin conditions appear to be distinctly better, although it must be admitted that here also there are many undernourished women and children. In any event, the condition of health has not been found to be so undermined that the patients in the institutions cannot retain their food. As a rule, more marked undernutrition was observed among the women, because they commonly deprive themselves of food, in the presence of a scarcity, in order that the men—the bread winners—and the children may not suffer a lack.

On the other hand, everywhere the peculiar observation has been made that unemployment in itself has not yet led to a marked lowering of the condition of health of the population. The person who is out of employment is often able to live a healthier life than when employed; he gets more fresh air and outdoor exercise, and has an opportunity to get all the sleep and rest he needs. These factors serve to counteract in a measure the effects of poor and inadequate food.

In the smaller towns and in the rural districts, where public aid is less organized, such conditions may be found when the unemployment has lasted for many months. Then, too, there are extensive districts in which tobacco workers have usually been poorly nourished and in an undermined condition of health. Furthermore, workers in these regions, in contrast with other industrial centers, suffered earlier from unemployment, because, on account of the strict limitation of the importation of foreign tobaccos, many whole factories have had to close down. But such conditions are rather the exception. Taking the population of the *reich* as a whole, the present state of nutrition of the German people is not unfavorable. Last year the federal public health service rendered to the reichstag a report on the state of nutrition of Germany's population, extending up to January, 1931. This report was surprisingly favorable. Nor has this year—thus far, at least—brought any information of a general lowering of the state of health. Likewise, the deaths from tuberculosis, the spread of which is usually furthered by defective nutrition, show a downward trend.

There is, to be sure, a wide range between undernutrition and death. Exact data on the nutritional conditions are received by the federal public health service only once a year in the reports of the *länder* and of their subdivisions. In view of the ever widening economic crisis, the authorities have decided to institute an inquiry now and not wait until the end of the year. The results of the inquiry will be published in September. It will then be seen whether or not the conditions reported from Hanover have spread to other sections.

Decline of Venereal Diseases

In a recent report published by the Deutsche Gesellschaft zur Bekämpfung der Geschlechtskrankheiten, Dr. Roeschmann tells of the effects of the federal law pertaining to the combating of venereal diseases, during the past five years. The recent census taken in Berlin, Altona and Magdeburg shows a marked decline in the incidence of such diseases. The municipal consultation centers are visited much more frequently than formerly. The law prohibiting quacks from treating persons with venereal disease has had a favorable effect. Also the sources of infection, toward which the authorities were formerly almost powerless, have been ferreted out much more successfully under the operation of the new law. The more direct relations established between the public health service and the medical profession by means of the social service organizations and the creation of treatment centers have been found to be valuable.

Limitation of Hospital Care

The Reichsausschuss für Aerzte und Krankenkassen has promulgated new regulations, which provide that hospital care shall be prescribed only when operations are involved that are generally performed only in clinics, or when, because of the nature of the malady or the special circumstances, the necessary and proper treatment can be given only in a hospital. Before hospital care is ordered, a careful inquiry must be instituted to discover whether or not, by calling in a specialist or by referring a patient to a specialist for treatment, hospital care can be avoided; whether domiciliary care will not take the place of hospital care, and whether admission to an infirmary or to an old people's home is indicated. The reasons for prescribing hospital care should be stated in the order. In cases involving danger to life, in cases in which invalidity threatens, and in communicable diseases the scientific diagnosis of the disease suffices as justification. Hospital care—aside from urgent cases—will be approved by the *krankenkasse* only when its consent has been secured before the patient has been admitted.

The New University Women's Hospital

Visitors in Berlin who looked up the old Universitätsfrauenklinik in order that they might at least see the famous center that, through the untiring labors of eminent scientists, had become an institute of world renown, were surprised and disappointed when they entered the plain appearing buildings in Artilleriestrasse, whose external appearance was not at all in keeping with their scientific importance. The original clinic was established in 1818, and the buildings the reconstruction of which is now nearing completion were opened just exactly fifty years ago. In 1886, the large auditorium was added, and in 1910 the Ida-Simon-Stiftung. But in the main the rooms had remained unchanged, and it will be easily understood that, in view of the many great developments of medical research, they were no longer equal to modern demands.

It is not so surprising, therefore, that Professor Stoeckel, the present director of the Universitatsfrauenklinik, when, in 1925, he became the successor of Bumm, accepted the responsible post only on the condition that the clinic would be reconstructed and enlarged in keeping with its present importance. The economic disturbances of the past few years have been unfavorable to a realization of these plans. Finally, however, the new structure is nearing completion. In view of the limited funds that were available, what has been accomplished is deserving of the highest praise and recognition. The plans for the new building were worked out by the most intimate collaboration between clinicians and architects, during the years 1925-1927; and it must be admitted that, while the chief stress was put on the practical side, the esthetic was by no means neglected. Special difficulties arose in connection with the foundation, which necessitated the sinking of reinforced concrete caissons. The building has a skeleton steel structure, with a length of 135 meters.

On the main floor is the Policlinic, which is spacious enough so that women patients may receive individual attention. Adjacent is the admission room for parturients. Farther on come the bath rooms, the examining room and finally the delivery rooms—two for normal confinements, with six beds each, and a ward in which pathologic confinements are completed by operation. The students are separated from the operating room by a balustrade and thus view the operations from a point where all danger of the transmission of infections is avoided. The children's beds in the delivery rooms can be heated if desired. The rooms for puerperants have five beds each, and adjoining are the rooms for infants with a like number of beds. In order to prevent infection through visiting friends and relatives, the rooms for infants are separated by a glass partition from the visitors.

On the second floor are the gynecologic department with the sickrooms and the main operating room, in which three operations can be carried on simultaneously. On the third floor are the solarium, which may be used also in winter, and the gymnasium, which is utilized also as an instruction room.

The buildings are not yet entirely completed. The last section of the building, which is now being begun, will provide an inner transformation of the old building and several pavilions, and will doubtless be finished by April 1, 1933. The Universitätsfrauenklinik will have sixteen departments, and the university will then have a well equipped and sufficiently large Frauenklinik, with 250 beds in place of 150 as heretofore, and a clinic that, in a measure at least, does justice to the high scientific importance of the institute. The cost of the reconstruction will doubtless exceed $250,000.

The Nature of Immunity to Tuberculosis

Dr. Capuani presented recently to the Società di cultura medica Novarese a communication on immunity to tuberculosis. The immunity is demonstrable by evidence based on epidemiology, clinical observation and research. This immunity, which was regarded for a time as of a humoral nature, is no longer so considered owing to the discovery of tuberculous antibodies. The antibodies do not develop a true defense action. But in the organic humors there are other antibodies that do not effect deviation of the complement, although their lytic actions on the Koch bacillus cannot be doubted. The same thing applies to the lipolytic phenomena.

Phagocytosis is the chief cause of the formation of the giant cell and of the reproduction of the micro-organism and hence represents the point of departure of all histogenesis. Tuberculous immunity is, on the whole, not very active, and the results secured are limited. It is, however, advisable to conduct the campaign against tuberculosis in such a manner as to consider tuberculous immunity an important basis for action but without concealing the fact that more certain results can be obtained from prophylaxis. Hence the mode of action that takes advantage of both methods is to be regarded as ideal, since only by their combined influence can the epidemiologic problem of tuberculosis be handled to advantage.

Meeting of Medical Academies

The Accademia medica di Roma met recently under the chairmanship of Prof. Silvestro Baglioni. Calò spoke on the cultivation of embryonal tissues of the chicken and of tumor tissues in the plasma of animals that had been irradiated with roentgen rays. These experiments have shown that in the blood of irradiated animals special substances are present which exert a peculiar action on the growth of artificially cultivated tissues.

Silvestri reported a case of kala-azar in Rome in a man, aged 36. He called attention to the necessity of an early diagnosis, which is possible by means of splenic puncture.

Zagami dealt with the so-called vitamin of fecundity (vitamin E), to which attention has been called by Evans and Bishop.

Galamini administered alcohol and insulin to rabbits intravenously and found the resistance of the animals to the toxic action of the two substances increased.

The Accademia medica di Genova also held a meeting under the chairmanship of Professor Durante. Frola and Prussia spoke on the filtrability of the tuberculous virus. The experimental researches of these authors support the view that no virus is demonstrable, at least with the technic available.

De Martini spoke on the failures of therapeutic pneumothorax in gangrene of the lungs. This treatment is frequently followed by pleural complications that prove fatal.

Duties of Physicians in Penal Institutions

According to the new regulations in penitentiaries, as explained by Dr. De Crecchio to the Accademia delle scienze medico-chirurgiche of Naples, physicians of penal institutions are entrusted with the biologic study of the inmates. They must, above all, see that every inmate is classified and placed in the section that best accords with his antecedents and his history. No disciplinary treatment and no special rewards accorded by law may be applied to inmates without the approval of the physician. In addition to the psychopathic hospitals, the welfare institutions and the houses of correction, also the new institutions for persons with disease must be directed by physicians who have specialized in criminal anthropology. The sanatoriums, preventoriums and homes for convalescents, under military control, will admit the inmates of penal institutions who have tuberculosis.

The Medical Congress of Sicily

The ninth Congresso medico siciliano was held recently at Catania. Professor Muscatello presented a paper on acute conditions of the abdomen. He spoke of the high mortality after operations in acute abdominal conditions and explained it by the delay in resorting to an operation. Long waiting is always harmful; even when the abdominal attack terminates with recovery, it requires a long time. Professor Zurrica spoke on the varied symptomatology of acute abdominal conditions and concluded that the greater part of them are fatal unless there is early surgical intervention.

Professor Di Guglielmo spoke on "The Immunizing Treatment of Tuberculosis." He gave a survey of antituberculosis vaccination, explaining the more recent methods of vaccination and serotherapy, defining the limits of their application.

Professor Sagona considered the importance of the immunizing treatment of tuberculosis. He said that at present the question of Calmette vaccination is being carefully studied by suitable institutions and authorized specialists, although the time has not yet come to extend the use of the vaccine to general practitioners.

Professors Giuffrè, Morelli, Bilancioni, and others, participated in the general discussion.

Anesthesia

Professor Uffreduzzi, of the University of Turin, spoke at the ninth International Congress of Surgery on the subject of anesthesia and narcosis. He said that it is practically impossible, in view of the complexity of the problem, to give an exact opinion concerning the merits, the defects and the indications of the various methods. The indications for narcosis cannot be rigid but must change as the technic develops. The more recent tendency, which the speaker regards as justified, is to restore general anesthesia to its former place. The most perfect local or regional anesthesia does not prevent the psychic trauma and is hence always inferior to general anesthesia. In local anesthesia, muscular relaxation is never complete. Postoperative pneumonia is often observed in local anesthesia, owing to the mental depression to which this method may give rise. The narcosis is influenced by the nature of the disease and the area of the operation, as well as by the mental and physical character of the subject operated on. Chloroform should no longer be used, other than in special cases and with strict limitations. Ether still remains the basis of general anesthesia, as the anesthetic of current use, and especially as an effective method of completing gas anesthesia or local or basal anesthesia. The gases, from the point of view of toxicity, represent the most perfect method that has as yet been devised for anesthesia. When properly employed, they present no danger whatever and permit grave interventions under ideal conditions. Anesthesia with gases has been improved by modern apparatus that permits the simultaneous administration and the exact determination of the dosage of oxygen and of carbon dioxide, the administration of which is useful during and after anesthesia. Uffreduzzi emphasized that hospitals need specially trained assistants for the administration of anesthetics.

The topic was discussed also by Gamberini of Bologna, who considered more particularly ether anesthesia by the rectal route. This form of anesthesia, after a brief period of popularity, has today few supporters, owing to the many contraindications. With regard to rectal anesthesia by means of "avertin," the speaker concluded from his personal experience that it presents numerous advantages, and that while it may produce untoward incidents if it is used in the basal dose, they are never fatal nor more numerous than those that occur with other methods of anesthesia. The fatal complications attributed to "avertin" have occurred from the use of excessive doses, and, taken at the worst, the mortality is no higher than that due to ether.

The Interruption of Gestation from a Legal Point of View

At a recent meeting of the gynecologic section of the Royal Medical Society, the entire time was devoted to a debate on the subject of the interruption of gestation. The most important paper was by Dr. Balázs Kenyeres, professor of forensic medicine at the University of Budapest.

Paragraph 285 of the Hungarian penal code applies in part to cases in which a physician induces abortion in the interest of the mother on proper indications. Although this operation would not aim to kill the fetus, the act properly constitutes a deed against the life of the fetus. According to present legal conceptions, a uterine fetus is, from conception on, a living being, which has rights and toward which the state has its duties. The civil law may appoint a guardian for it if deemed necessary and put its expectable inheritance under juridical custody. On the same ground the penal law protects the life of a fetus against attacks threatening it, by regarding the induction of abortion as a crime against human life and prosecuting it as manslaughter. There is no difference between a life and life. The killing of a man sentenced to death, that of a dying man, that of an unborn baby, is just as much manslaughter as is the killing of any other man; the law refers to each of them uniformly, and there is no mention in the law that any of these would be allowable to serve other interests.

Of course, it does not follow that every person committing one of the foregoing crimes is punished. In certain cases either the general provision of the law or juridical practice may exempt one from punishment. The criminal is not punished if he commits the crime for averting a direct danger to the life of the mother. Other reasons for killing a fetus are not recognized by juridical practice. It is understood, humanly speaking, that the physician trying to help his fellow out of a desperate situation may even be exonerated; but he cannot claim exemption from the law on such grounds. If such causes insured exoneration, it would lead to incalculable abuses. The medical profession must demand its rights, which juridical practice grants, that, in order to save a pregnant woman's life or health which is endangered, the life of the uterine fetus should be sacrificed, but the demand cannot go further. Whoever commits abortion for other reasons has to answer for it according to law if the guilt is found out. The induction of abortion violates the interest of the medical profession and seriously damages the physician in question. It is a responsibility for a doctor to be the adviser and friend of a family, which entrusts him with the health and lives of its members, but this doesn't imply that he should help them in every way. If the physician assures an unmarried pregnant woman secrecy, or endeavors to help place the child when born, or tries to help her get work, he fulfils his trust; but he goes too far if he undertakes to do forbidden things. The physician who undertakes to induce abortion can never be sure whether it will not have serious consequences to the mother. Even with the most scrupulous technic, puerperal infection may occur causing the death of the woman, and in such a case, even if the operation was done for medical reasons, the charge of manslaughter caused by negligence may follow.

In regard to the indications for the interruption of gestation, all responsibility belongs to the physician. Between the unpunishable interruption of gestation and the crime of abortion the border is indistinct. If physicians do everything in their power to clear up the diagnosis and rigorously stick to the law, that the life of a fetus can be taken only to save the life of the mother, they need not be afraid of the law. But those who intentionally try to cloak with fictitious indications their deeds committed from other motives should not reckon on support from those versed in legal procedure.

Marriages

ALTON BROOKS FREEMAN, Randleman, N. C., to Miss Elizabeth Breeden Townsend of Dunn, July 15.

HENRY HOWARD WHITEHOUSE, New York, to Miss Carolyn Harding Beebe at Mystic, Conn., July 9.

WILLIAM DAVID STRAYHORN, JR., Nashville, Tenn., to Miss Mary Blalock of Jonesboro, Ga., July 2.

WILLIAM EDGAR VADEN to Mrs. Majorie Yearby Hood, both of Chattanooga, Tenn., in July.

DONALD A. MCLANE to Miss Gertrude Marie McKenna, both of Englewood, N. J., July 15.

CHARLES FRANCIS DE GARIS, Baltimore, to Miss Ethel Virginia Price, June 15.

Deaths

Clement Frank Theisen, Albany, N. Y.; Albany Medical College, 1892; member of the Medical Society of the State of New York; member of the American Laryngological Association; formerly clinical professor of laryngology and rhinology at his alma mater; on the staffs of the Child's Hospital, St. Peter's Hospital and the Brady Maternity Hospital; aged 61; died suddenly, July 27, of coronary sclerosis, chronic myocarditis and arteriosclerosis.

Charles Joseph Durand ⊕ Colfax, Calif.: Laval University Faculty of Medicine, Quebec, Que., Canada, 1911; fellow of the American College of Physicians; past president of the Placer County Medical Society; health officer of Colfax; for many years assistant medical director of the Colfax School for the Tuberculous; aged 45; died, July 6, in Sacramento, following an operation for inguinal hernia.

Peter Leo Dorey ⊕ Middlebury, Vt.; University of Vermont College of Medicine, Burlington, 1904; past president of the Addison County Medical Society; on the staffs of the Fanny Allen Hospital, Winooski, Porter Memorial Hospital, Middlebury and the De Goesbriand Hospital, Burlington; aged 56; died, June 17, of cardiorenal arteriosclerosis and pulmonary embolism.

John Leonard Everlof ⊕ Minneapolis; Jefferson Medical College of Philadelphia, 1916; fellow of the American College of Surgeons; served during the World War; associate attending genito-urinary surgeon to the Minneapolis General and Swedish hospitals; aged 43; died, July 12, of chronic glomerulonephritis.

John Edwin McKillop ⊕ Los Angeles; Medical Department of the University of California, San Francisco, 1911; professor of medicine (communicable diseases), College of Medical Evangelists; on the staff of the Los Angeles General Hospital; aged 48; was accidentally drowned, July 25.

Charles Ephraim French ⊕ Lowell, Mass.; University of Maryland School of Medicine, Baltimore, 1893; member of the New England Ophthalmological Society and the New England Otological and Laryngological Society; aged 64; died, July 6, in the Shaw Hospital, of shock following prostatectomy.

Myron Botsford Palmer ⊕ Rochester, N. Y.; University of Pennsylvania School of Medicine, Philadelphia, 1899; member of the American Roentgen Ray Society; aged 58; died, July 24, in the Strong Memorial Hospital, of appendicitis, intestinal obstruction, paralytic ileus and peritonitis.

John Angus Macdonald, Vancouver, B. C., Canada; L.R.C.P., Edinburgh, Scotland, 1881; Faculty of Medicine of Trinity College, Toronto, 1881; formerly member of the provincial board of health of Manitoba and city health officer of Brandon; aged 69; died, April 28, of pneumonia.

Sidney James Watson, Worthington, Minn.; University of Minnesota Medical School, Minneapolis, 1927; member of the Minnesota State Medical Association; on the staff of the Worthington Clinic Hospital; aged 27; died, in July, of septic sore throat and heart disease.

Haldor Louis Gahm ⊕ Washington, D. C.; Ohio State University College of Medicine, Columbus, 1912; member of the Ohio State Medical Association; served during the World War; aged 45; died, August 2, in U. S. Veterans' Hospital number 32, of carcinoma.

William Palmer P. Kirby, Moncton, N. B., Canada; McGill University Faculty of Medicine, Montreal, Que., 1908; fellow of the American College of Surgeons; aged 50; senior surgeon to the Moncton Hospital, where he died, May 22, of cerebral hemorrhage.

Thomas Jefferson Tribble, Nederland, Texas; Memphis (Tenn.) Hospital Medical College, 1907; member of the State Medical Association of Texas; for many years health officer of Sabine Parish; aged 52; died, May 23, of cardiovascular hypertensive disease.

David Crockett Walt ⊕ Little Rock, Ark.; Memphis (Tenn.) Hospital Medical College, 1884; formerly professor of clinical medicine and associate professor of anatomy, College of Physicians and Surgeons, Little Rock; aged 68; died, July 22, of carcinoma.

W. T. Pace, Smyrna, Ga.; Georgia College of Eclectic Medicine and Surgery, 1887; member of the Medical Association of Georgia; formerly member of the state legislature; aged 69; died, July 26, in a hospital at Marietta, of carcinoma of the prostate.

Charles Eggleston Hooker, Grand Rapids, Mich.; University of Michigan Medical School, Ann Arbor, 1895; member of the Michigan State Medical Society; chief of staff of the Blodgett Hospital; aged 60; died, August 3, of heart disease.

Charles J. Vaughan, Atlanta, Ga.; Atlanta Medical College, 1893; member of the Medical Association of Georgia; aged 75; died, July 21, in the Georgia Baptist Hospital, of uremia resulting from chronic nephritis and prostatic hypertrophy.

David William Howell, Caney, Kan.; Medico-Chirurgical College of Kansas City, Mo., 1902; member of the Kansas Medical Society; past president of Montgomery County Medical Society; aged 66; died, June 17, of cerebral hemorrhage.

Charles Melville Whitney ⊕ Boston; Harvard University Medical School, Boston, 1887; professor of urology, Tufts College Medical School; member of the American Urological Association; aged 69; died, July 30, of heart disease.

Arnold August Scherr, Keyser, W. Va.; College of Physicians and Surgeons, Baltimore, 1903; member of the West Virginia State Medical Association; served during the World War; aged 54; died, May 27, of coronary sclerosis.

Edmund Dozier Hunter, Norfolk, Va.; College of Physicians and Surgeons, Baltimore, 1901; member of the Medical Society of Virginia; aged 60; died, June 28, in a local hospital, of chronic interstitial nephritis.

Isaac N. Freeman, Hot Springs National Park, Ark.: Gate City Medical College, Texarkana, Texas, 1905; member of the Arkansas Medical Society; aged 66; died, June 20, of cerebral hemorrhage.

Clayton Ross Entwistle, Philadelphia; Tufts College Medical School, Boston, 1919; aged 36; on the staff of the Memorial Hospital, where he died, July 18, of subarachnoid hemorrhage.

Robert W. Rowland, Flora, Miss.; Hospital College of Medicine, Louisville, 1877; member of the Mississippi State Medical Association; aged 76; died, in April, of pulmonary tuberculosis.

George W. Scruggs, Humnoke, Ark.; National Normal University College of Medicine, Lebanon, Ohio, 1891; member of the Arkansas Medical Society; aged 63; died, June 21, of paralysis.

Solomon Matthews Dorland, Rodney, Ont., Canada; Faculty of Medicine of Trinity College, Toronto, 1884; aged 84; died, May 29, of carcinoma of the stomach.

William Milton Rose ⊕ Cambridge, Mass.; Tufts College Medical School, Boston, 1903; aged 74; died, March 24, of chronic myocarditis.

John Q. Elmore, Gordon, Neb.: Medical Department, University of Tennessee, Nashville, 1888; aged 81; died, June 8, of heart disease.

Alfred Winthrop Bowman, Arlington, Mass.; Harvard University Medical School, Boston, 1901; aged 53; died, June 7, of heart disease.

H. Coford Johnson ⊕ San Francisco; Medical Department of the University of California, 1908; aged 48; died, July 8, of typhoid.

Giles Benjamin Wood, Burke, Texas; licensed, Texas, under the Act of 1907; aged 71; died, May 12, of atrophy of the liver.

Dana G. Cook, Albion, Mich.; Fort Wayne College of Medicine, 1897; aged 75; died, July 28, of arteriosclerosis.

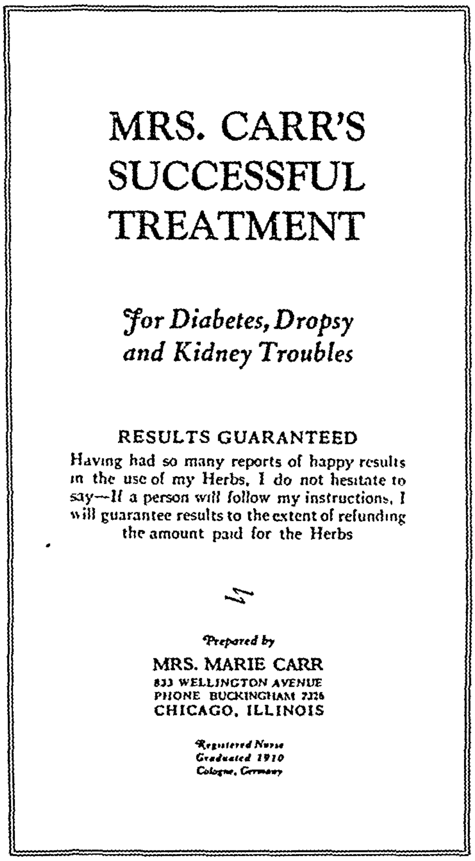
Bureau of Investigation

THE MARIE CARR FRAUD

A Crude Piece of Mail-Order Quackery Barred from the United States Mails

During the past few years, a Chicago woman calling herself "Mrs. Marie Carr" has been selling on the mail-order plan alleged cures for diabetes, Bright's disease, sexual debility, obesity and many other conditions. Marie Carr actually was the maiden name of a Mrs. P. P. La Plant, who was not a physician, pharmacist or a chemist, and employed no one having these qualifications. On her letterheads and in her advertising, she claimed to be a registered nurse who was graduated in 1910 at Cologne, Germany.

In 1928, she was sending out letters addressed to the superintendents of various industrial concerns, urging that these superintendents should distribute her advertising folders, so that any men in the plant who might be suffering from diabetes or Bright's disease might know where they could get relief!



MRS. CARR'S
SUCCESSFUL
TREATMENT

*For Diabetes, Dropsy
and Kidney Troubles*

RESULTS GUARANTEED

Having had so many reports of happy results in the use of my Herbs, I do not hesitate to say—If a person will follow my instructions, I will guarantee results to the extent of refunding the amount paid for the Herbs

Prepared by

MRS. MARIE CARR
833 WELLINGTON AVENUE
PHONE BUCKINGHAM 2326
CHICAGO, ILLINOIS

*Registered Nurse
Graduated 1910
Cologne, Germany*

In February, 1932, Mrs. La Plant was furnished by the Post Office Department with a memorandum of charges and she was called on to show cause by March 22 why a fraud order should not be issued against her. Mrs. La Plant on March 7 wrote to Washington, denying the charges and stating that she was unable to appear in Washington or to employ counsel. She was then given the opportunity of voluntarily abandoning her fraudulent business and was granted an extension of time to March 31 to file an affidavit covering the matter. Following this, Mrs. La Plant engaged a lawyer and, at his request, the date for filing the affidavit was postponed to April 18. By April 26, nothing further had been heard from either Mrs. La Plant or her attorney and the government notified the woman that the matter would be disposed of in the usual manner. That communication was also ignored.

According to the memorandum of Judge Horace J. Donnelly, Solicitor for the Post Office Department, to the Postmaster General, recommending the issuance of a fraud order, Mrs. La Plant's enterprise consisted in the sale through the mails of herb-tea preparations that she claimed would cure or relieve such ailments as diabetes, Bright's disease, sexual debility, obesity, dropsy, jaundice, liver trouble, rheumatism, gallstones, female trouble, asthma, gonorrhea, etc. Mrs. La Plant obtained business by running advertisements in various magazines and periodicals, as well as by sending circulars and other matter through the mails. The advertisements were rather typical of crude "patent medicine" quackery. The story was to the effect that the "monks of old," and also the Indians of many years ago, practiced medicine long before doctors were known; that they would gather leaves, barks, wild berries, and roots, make a tea of them, and produce remarkable cures. Mrs. La Plant then went on to state that she had obtained certain formulas, which had been in use for more than two hundred years, and was importing the herbs, which she combined in the dried and crushed form and in proper proportions. The government found that this woman did not import her herbs at all but purchased them from a concern in Hammond, Ind.

One of the herb teas which was sold as a "cure" for diabetes and Bright's disease was known as "Formula No. 232." Mrs. La Plant, in letters to those supposedly suffering from diabetes, urged them to discontinue the use of insulin when they began using her herbs. Microanalysts for the government reported that Mrs. La Plant's No. 232 consisted of a mixture of sassafras bark, marshmallow root, couch grass, juniper berries and round dock. Judge Donnelly pointed out in his memorandum to the Postmaster General that diabetes and Bright's disease are two totally different diseases and call for different treatment.

The herbs for sexual debility and, incidentally, for "night sweats," were called by Mrs. La Plant "Formula No. 114." This was said to restore "lost manhood." The government microanalysts found that No. 114 contained fennel seed, bearberry leaves, gentian root, red clover flowers, round dock, mullein leaves and sage leaves. It was shown at the hearing that such a combination would have no other effect than that of a diuretic and bitters and contained nothing that could prove curative or beneficial to those suffering from sexual debility.

The obesity treatment, known as "Formula No. 56," was found to contain bladderwrack, horsetail, celery seed, pumpkin seed, sassafras bark, and angelica root. As with most quack "obesity cures," when the victim had paid for the medicine and received the package, he was told that it was necessary to omit from the diet a number of foods, and was also told to take certain exercises.

In view of the obvious fraudulence of the scheme, the Solicitor's memorandum recommended that the Postmaster General issue a fraud order. It was issued on May 31, 1932.

WACK'S GALLBLADDER CAPSULES

Norman A. Wack, a druggist of Wayne, Pa., puts out a preparation called "Gallbladder Capsules" that are sold on the mail-order plan. Because of the inquiries received, an original package of the Gallbladder Capsules was purchased direct from Norman A. Wack and was submitted by the Bureau of Investigation to the A. M. A. Chemical Laboratory for investigation. The package contained 104 capsules (pink in color) filled with colorless, odorless crystals having a slight saline taste. The Laboratory reported that the contents of the capsules varied in weight about 24 per cent, the average being about 6¼ grains. No information was given as to their composition.

On examination, the A. M. A. Chemical Laboratory reported in part as follows:

> "Qualitative tests indicated the presence of sodium and an organic acid, indicative of succinic. Alkaloids, halides, sulphates and heavy metals were not found. On heating the product in an electric oven at 100 C. for six hours, it lost 40 per cent in weight; and on further heating, it remained constant. This is characteristic of sodium succinate hydrated. The amount of 'sulphated' ash obtained was 85.9 per cent, which is equivalent to 27.8 per cent calculated as sodium. These figures also agree with those for sodium succinate hydrous. In addition, a specimen

of Wack's Gallbladder Capsules was sent to a petrographer for comparison by optical methods with a known specimen of pure sodium succinate (hydrous). The petrographer reported that the two substances were found to be identical.

"From the foregoing, it was concluded that the contents of Wack's Gallbladder Capsules were essentially sodium succinate."

From the chemists' report, it appears, therefore, that Mr. Wack was dispensing about 700 grains of sodium succinate in crudely filled capsules. For this he charged $3. Sodium succinate can be purchased at $1.37 a pound. This means that twenty cents would be a liberal estimate of the actual cost of the material for which Mr. Wack charges the public $3. While, in the past, sodium succinate has been held by some to have value in the treatment of cholecystitis, there has never been developed any scientific evidence to support the claim.

THE OSCILLOMETRIC INDEX PROXIMAL TO VASCULAR OCCLUSION

To the Editor:—In reviewing oscillometric curves taken at various levels in cases of thrombo-angiitis obliterans as well as in cases of peripheral thromboses and emboli, and comparing these readings at corresponding levels in the unaffected limb, an interesting observation was made. It was noted that the oscillometric index at the point just proximal to the point of occlusion was definitely and consistently larger than the index at the same level in the unaffected limb. This did not hold true when the obstructive lesion was sclerotic in character.

An explanation of this phenomenon is seen when one reviews the hydrodynamics of the peripheral circulation, so well described by Dr. W. Wayne Babcock (*Am. J. Surg.* **16**: 401 [June] 1932). When the velocity of the blood flow is increased, the wall pressure decreases. With occlusion of the vessel, the blood flow velocity is decreased to zero and therefore the wall pressure is definitely increased.

This small point is of great value in the differential diagnosis of peripheral vascular disease, for in cases of spastic vascular occlusion the oscillometric index is lower proximal to the lesion, compared with the unaffected limb, than it is in the arteriosclerotic type of vascular occlusion.

William C. Beck, M.D., Sayre, Pa.
From the Guthrie Clinic.

REACTION AFTER INJECTION OF NUPERCAINE

To the Editor:—A woman, aged 55, applied for treatment of piles, usually taken care of by local anesthesia, submucous infiltration and removal either by excision or by surgical diathermy. The patient, who was in general good health, weight about 125 pounds (57 Kg.), and of nervous temperament, was prepared in the usual way, and 1 per cent nupercaine, freshly made, was injected subcutaneously and submucous to the local pile area in the amount of 5, but not more than 6, cc. A reaction of dizziness and nausea set in before any other procedure began, followed by vomiting and loss of bladder and rectal control and unconsciousness. This occurred at about 8 o'clock and this state prevailed until 3 a. m., when a rational state began. The following day the patient complained of dizziness and nausea. There were signs of decreased reflexes. The pupils were dilated. The pulse was 64 and the patient was pale. During the acute stage there was a primary flushing of the skin surfaces, the pulse was rapid and thready, the pupils were dilated, and this condition was succeeded by marked pallor, profuse prespiration, and a pulse of 60, small of volume. The patient states that years ago she noticed ringing in the ears with use of quinine.

V. W. Jensen, M.D., Shelby, Mich.

SIMULTANEOUS HOMOLOGOUS DISLOCATION OF HIP IN TWO PATIENTS

To the Editor:—Dislocations of the hip are uncommon injuries and, according to Wilson and Cochrane, form only about 2 per cent of all dislocations. A hip dislocation, however, is not in itself a notable occurrence. To have a man of 37 and a girl of 25 riding in a light coupé strike a tree and both receive a posterior dislocation of the right hip must surely be rare.

The couple left a camp to drive to town in a somewhat intoxicated state and on a sharp turn of a narrow road the car veered to the right, striking a tree between the right fender and hood. The car was demolished. Both were brought to the hospital semiconscious, with multiple scalp wounds. The man had also several broken ribs. Both presented a classic flexion and adduction deformity of the right thigh, and both showed a posterior hip dislocation without fracture in the x-ray films. Both dislocations were easily reduced. The patients were placed on the floor and the thigh and knee sharply flexed, strong upward traction being made on the thigh, with counterpressure on the pelvis. Both patients have made uneventful recoveries from their hip injuries.

R. J. White, M.D., Fort Worth, Texas.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

DIARRHEA IN CHILDREN

To the Editor:—A child of 13 months, in good vigorous health, two and a half months ago developed an acute diarrhea apparently rather mild in character. The rectal temperature rose to 101 F. Recovery occurred with simple treatment in one week. A recurrence in about five days followed the apparent recovery. The recurrence seemed identical to the first attack. The stools were watery and green, and they contained mucus and curds. Only weak tea and water were given for twenty-four hours, with marked improvement. Then boiled skimmed milk and water in equal parts, cottage cheese, jello and plain toast were added, followed gradually by the farinaceous foods, buttermilk, custard puddings and tomato juice. A formula of boiled skimmed milk and protein milk, mixed together, was used; later, vegetable water, and sieved banana in small quantities. The stools have continued at five or six a day for the last six weeks, containing mucus and a few pus cells positive for occult blood. Macroscopic blood was observed in only two stools. The Welch bacillus was isolated from the stool. The child plays and seems quite happy; the general condition is excellent. The only drug treatment has been the recent use of kaolin for a few days at a time, alternating with tincture of iodine for a like period. Are there any suggestions for treatment at this time? Is this likely to become a case of chronic ulcerative colitis? Please omit name.

M.D., California.

Answer.—A subacute or chronic diarrhea occasionally follows an acute attack in children under 2 years of age. This is usually more in the nature of a catarrhal enteritis and only rarely develops into chronic ulcerative colitis. Occult blood, mucus and occasional pus cells, as in this case, may be present in the stools in a simple catarrhal enteritis or colitis without gross or macroscopic ulceration. Although the excellent general condition and happy disposition of the child virtually rules out any serious type of infection, the stools should be carefully examined and cultures should be taken for dysentery, amebic and bacillary, the typhoid groups and the ova of intestinal parasites. Tuberculous enteritis can easily be excluded by a negative tuberculin skin test.

In the treatment the diet should not be restricted too severely and the caloric intake should be enough to insure proper gain of weight. Generally speaking the diet should be low in fat content (cream and butter sparingly), high in protein (scraped meat, cottage cheese, beef juice, gelatin, eggs), bland without roughage (all vegetables puréed and those that seem to aggravate the diarrhea eliminated entirely), no fruits except orange juice, scraped raw apple and mashed ripe banana. Mashed banana is an excellent starchy food in these cases of diarrhea and should be given as a substitute for cereal early. Later the finer cereals, as farina and cream of wheat, may be added. Oatmeal and wheatena are to be avoided because of their increased laxative properties. Lactic acid milk, at first skimmed and later whole, should be tried, or protein milk. If the child refuses the sour milks, boiled skim milk with casein added may be used.

Regarding medication, if a mixture of camphorated tincture of opium, 0.6 cc., and bismuth subcarbonate, 0.6 Gm., four times daily does not control the diarrhea, a tannic acid-proteinate such as albumin tannate, 0.3 Gm., three times daily, often proves efficacious.

CAUSTIC ACTION OF PAINT REMOVER

To the Editor:—I am very anxious to learn, if possible, the ingredients which go to make up a paint remover marketed under the name of "Lucas (semipaste) Mirac Varnish and Paint Remover," manufactured by John Lucas & Co., Inc., Philadelphia, New York, Chicago, Boston, Pittsburgh and Oakland, Calif. A present patient of mine had some of this material splashed into his eyes about two years ago and a medicolegal question arises as to whether any of the ingredients in the paint remover were caustic in their action on tissues.

Nelson M. Black, M.D., Miami, Fla.

Answer.—The term "caustic" is definable in so many ways that it is appropriate to regard all chemical paint removers as containing constituents that exert caustic action on tissues of the eye. This assumes that caustics are defined as substances capable of destructive action on living cells. If, however, caustics are regarded as corrosives or escharotics, it is unlikely that the semipaste types of paint remover will contain caustics.

Lucas Mirac Varnish and Paint Remover is believed to be similar to that made by many other paint manufacturers operating under the Chadeloid patents. The formulas are not constant. They may contain benzene, benzine, amyl acetate, ethyl acetate, acetone, propyl alcohol, methyl alcohol (wood alcohol), carbon bisulphide, paraffin, soaps, beeswax or petrolatum. A typical formula is benzine 200 parts, denatured alcohol or wood alcohol 200 parts, acetone 50 parts, paraffin 25 parts, alkali soaps 25 parts, carbon bisulphide 25 parts, amyl or ethyl acetate 5 parts, and beeswax 5 parts. The paraffin, beeswax, petrolatum and soaps are used to produce the jell or semipaste consistency.

Several of the substances mentioned are capable of inducing injuries to the eyes. If optic atrophy is present, investigation should include the possibility of damage arising after the inhalation of wood alcohol or carbon bisulphide vapors over an extensive period. This form of damage is to be regarded as an occupational disease rather than as an accidental injury.

SENSITIVITY TO CINCHONA DERIVATIVES

To the Editor:—A patient with paroxysmal auricular fibrillation has been controlled with quinidine for about two years. Lately, however, the taking of a small dose by mouth (he uses capsules) causes intense nausea and faintness with a still successful result in timing the rhythm. He has evidently developed an idiosyncrasy. 1. Would all the related cinchona derivatives cause the same toxic symptoms? 2. Is there any other method of administration (parenteral) for quinidine or suitable substitute? 3. Are toxic symptoms due to direct gastric irritation or are they due to effect on venous structures after absorption?

Lawrence S. Ward, M.D., Bronx, N. Y.

Answer.—1. Among the recognized untoward effects of quinidine is nausea, even vomiting, with faintness and dizziness. The other cinchona derivatives act qualitatively alike but differ quantitatively, so that quinine may possibly be tolerated with benefit.

2. The quinidine acid hydrochloride, soluble in 4 parts of water, might be used intramuscularly in doses of 0.3 Gm. in 2 cc. of water, or intravenously in 5 cc. of water.

3. The nausea may be due to stimulation of the vomiting center.

LATE SYPHILIS OF CENTRAL NERVOUS SYSTEM

To the Editor:—This inquiry concerns late cases of syphilis with definite brain and spinal cord involvement, such as are found in mental institutions, and refers to the recognized or authoritative opinion on treatment of cases other than with malaria. Am I wrong in the opinion that neurologists and psychiatrists generally do not consider arsenicals, bismuth preparations, or mercurials of much value? And is the same opinion held by syphilologists generally? Might more harm than benefit result from the fibrolytic action of potassium iodide, given either continuously or interruptedly, about ninety drops of saturated solution a day? Please omit name.

M.D., Pennsylvania.

Answer.—It is difficult to say just what a neurologist and psychiatrist in general considers as adequate treatment for late cases of syphilis of the brain and spinal cord. Opinions vary, and the views on the whole subject are undergoing constant change. Psychiatrists and neurologists divide syphilis of the central nervous system into mesoblastic and parenchymatous types. Some of the forms of mesoblastic types are syphilitic endarteritis, meningitis and multiple small gummas. The parenchymatous types are classified as dementia paralytica, tabes, and dementia paralytica with tabes.

There is probably no disagreement between neurologists and psychiatrists on the one hand, and syphilologists on the other, that all cases of mesoblastic syphilis of the nervous system should be treated with mercury preparations, bismuth compounds, arsphenamine or one of its substitutes, and potassium iodide. The usual dose of the last named drug is from fifteen to fifty drops of a saturated solution three times a day. This drug reduces the antitryptic index of the blood and probably produces some fibrolytic action. If it is pushed too much in cases of endarteritic cerebrospinal syphilis, cerebral hemorrhages have been known to result. If a patient suffering from mesoblastic syphilis of the central nervous system does not respond to these forms of treatment, psychiatrists, neurologists and syphilologists are inclined to substitute tryparsamide in place of arsphenamine; yet some have a distinct dislike for this drug because of its well known action on the optic nerve. It often produces transitory toxic amblyopias, and even occasional blindness has resulted from its use.

In treating parenchymatous syphilis of the central nervous system, modern psychiatrists and neurologists are generally convinced that treatment with anything less than bismuth or mercury compounds, potassium iodide and tryparsamide is useless. Syphilologists have a tendency to cling to the same treatment in these forms as has been described as the treatment for mesoblastic syphilis of the central nervous system.

The most modern treatment for dementia paralytica and dementia paralytica with tabes is undoubtedly some form of fever therapy.

BURNS WITH HYDROFLUORIC ACID

To the Editor:—Last November a patient came to me complaining of a burn the size of a quarter on the anterior surface of the right forearm, the result of having dropped a small amount of hydrofluoric acid on her arm. It required six weeks to heal the wound, and the patient complained of severe burning pain throughout the treatment and some time afterward. Yesterday the patient returned complaining of pain, tenderness and a burning sensation involving the skin over the terminal phalanges of the fingers of the right hand. The involved areas are red, hot and apparently very tender. The finger nails are raised and seem to be loose. The nails on the other hand are normal. Except for the condition of the nails, one would guess that the patient had a first degree burn of the fingers. She has not worked with hydrofluoric acid since November, and she states that she has not injured her fingers in any way. She feels that the present condition is secondary to the original burn. Could this be possible? What in your opinion is the cause of the present condition and what treatment would you recommend? What is the best method for treating hydrofluoric acid burns? Please omit name and town.

M.D., West Virginia.

Answer.—There is no special treatment for a burn caused by hydrofluoric acid—that is, after the burn has really occurred. The condition of the hand, fingers and finger nails, suggests the possibility of malingering. The latter should be carefully excluded. It should also be definitely ascertained whether the patient's hand is coming in contact with any chemicals to which the skin has become sensitized, thereby producing dermatitis venenata. In the meantime, proper treatment would seem to be soothing agents, such as calamine lotion in the day time and zinc oxide ointment at night.

BENZENE POISONING

To the Editor:—My attention was recently called to a postmortem case. A man, aged 36, had worked for a year in a rubber plant where he came in contact with benzene (benzol), a form of naphthol, constantly. When he accepted the position he was in the best of health, having formerly been a blacksmith. He gradually became weak and very anemic, and arthritis developed in the knees and ankles, with some synovitis. The postmortem examination disclosed subacute yellow atrophy of the liver with regeneration. The contributory cause was confluent hemorrhagic bronchopneumonia. Are there many cases like this? Where can I get literature on the subject? Please omit name.

M.D., California.

Answer.—Benzene (benzol) is not a form of naphthol. The postmortem appearances as well as the clinical state mentioned are reasonable results of the action of benzene. Hemorrhage is a characteristic feature of chronic benzene poisoning.

In the final report of the "Benzol" (benzene) Committee (Final Report of the Committee on Benzol [Chemical and Rubber Sections], National Safety Council, Chicago, May, 1926) may be noted many cases similar in some respects to the one in this query. In a publication by McCord (Benzol [Benzene] Poisoning: A New Investigation of the Toxicity of Benzene and Benzene Impurities, ed. 2, Industrial Health Conservancy Laboratories, Cincinnati, 1932) may be found an extensive literature citation to all aspects of benzene poisoning. Hemorrhage, hemorrhagic pneumonia and liver damage after benzene poisoning are discussed in these cited publications. A few diseases unrelated to industry may produce the conditions mentioned in the query. In the main, these are the result of blood dyscrasias of bacterial origin.

EFFECTS OF INDUSTRIAL POISONS AND IRRITANTS ON LUNG

To the Editor:—A man, aged 33, in normal health to December, 1931, had a cold and cough which did not clear up. The first physician consulted made a diagnosis of bronchitis. No improvement resulting after treatment for a month, a second physician was seen, who called it asthma. The patient's condition became worse and a third physician, after a roentgen examination, told him he had acute miliary tuberculosis. Two other roentgenologists have seen the films and both agreed that it was not tuberculosis. One favored silicosis, the other thought it might be a fungous infection. The patient has paroxysms of coughing, which are worse in the early morning. He raises from 4 to 6 ounces of thick tenacious sputum in twenty-four hours. Some days there will be a considerable amount of blood in it; other days, little or none. Respiration is about 30, asthmatic and abdominal in type. The patient cannot breathe lying down and sleeps sitting in a chair. Dyspnea is more marked toward night and in damp weather. The temperature has not been above normal. Ten specimens of sputum have been negative for tuberculosis. The leukocyte count was about 9,000. The Wassermann reaction has been taken but no report has been made. The patient's normal weight is about 150 pounds (68 Kg.). He had lost about 15 pounds up to a month ago and there has been no change since. On one side of his neck just above the clavicle there are two enlarged glands, each about the size of a small acorn. There is one on the opposite side in the same location. There are no enlarged axillary glands. One epitrochlear and a few inguinal glands were palpable. The chest showed loud, moist râles, more profuse over the upper half. There are areas where the expiratory sound is prolonged. Resonance does not seem abnormal. The important points in the past history are in the patient's occupation. For two years, about eight or ten years ago, he worked around a stone crusher. For the last eight years he has been exposed a great deal to the fumes of gasoline while cleaning out tank cars. Will you discuss the differential diagnosis and treatment? Also the effect on the lungs of long continued exposure to the fumes of gasoline. Please omit name.

M.D., Maine.

ANSWER.—The cause of the clinical picture here presented probably is no single agent, such as naphtha or silica, and is instead to be found in the combination of several, acting in complex fashion.

Work for two years, ten years ago, about a stone crusher, without intervening symptoms, still permits of the assumption of the formation of an abnormal amount of fibrous tissue. This rock dust is important in proportion to the amount of free silica present and to the amount of dust actually taken into the lungs during the two years. Two years is a relatively short exposure in connection with the expectancy of silicosis production. However, any degree of silicosis then inaugurated may be expected to progress (Britton, J. A., and Head, J. R.: Pneumonoconiosis: The Delayed Development of Symptoms, THE JOURNAL, June 6, 1931, p. 1938). The radiographic observations in silicosis are essentially characteristic. With reference to the conditions found in early cases, the American Public Health Association's committee on silicosis said: "The earliest specific indication of the presence of silicosis is the radiographic appearance, consisting of generalized arborization throughout both lung fields with more or less small, discrete mottling. This characteristic mottling is due to shadows cast by the discrete individual nodules of fibrous tissue in the lungs, and is essential to the diagnosis of silicosis during life." A further advanced silicosis may present fusion of many nodules, but some discrete ones will remain. This roentgenographic feature may in this case determine the part played by silicosis.

Gasoline vapors are definitely toxic, and the cleaning of tank cars is one of the most promising opportunities for exposure, unless workers are provided with hose masks with air pumped in from outside the tank car. The manifestations do not well suggest naphtha (gasoline) poisoning. Commoner developments are "naphtha jags," in which, as an acute result of naphtha intake, the worker acts in a manner closely simulating alcoholic intoxication. In other instances the worker may develop acute or chronic dermatitis. Others present acute inflammation of the respiratory tract, with chief involvement in the upper portion. Long sustained exposure may induce a chronic process with associated bronchiectasis. Bronchiectasis is undoubtedly present in this case. True, chronic naphtha poisoning is more likely to involve the central nervous system, leading to a clinical picture simulating multiple sclerosis. A hepatitis may coexist. Without some of the aforementioned, naphtha may not be rightfully associated as a major factor in the present case. An exception may reside in the fact that naphtha may so injure the tissues of the body as to form what loosely may be termed a "naphtha proteinate." By this the body may be sensitized and, theoretically at any rate, much of the patient's condition may be accounted for on this presumption. A skin patch test with naphtha may establish sensitivity.

A primary infection by fungi, leading to a bronchomycosis, provides a tenable explanation of this case. The characteristics and differentiation of such an entity have been presented by Edward Steinfield (Bronchomycosis Associated with Certain Types of Bronchial Asthma, THE JOURNAL, Jan. 12, 1924, p. 83) and by W. D. Stovall and H. P. Greeley (Bronchomycosis, THE JOURNAL, Nov. 3, 1928, p. 1346). An allergic state due to a mycotic infection in another portion of the body, such as the feet, may be regarded as a further reasonable possibility.

Treatment for this condition naturally will depend on the making of a more nearly exact diagnosis than appears to exist now. Both for diagnosis and for treatment, much may be gained by washing the lung, followed by injections of iodized oil.

ACETARSONE (STOVARSOL) IN AMEBIASIS

To the Editor:—I have received a circular from Merck & Company recommending the use of stovarsol in amebiasis. Will you please comment on the value of such medication? Please omit name.

M D, California.

ANSWER.—Acetarsone ("Stovarsol"), acetylaminohydroxyphenylarsonic acid, containing from 27.1 to 27.4 per cent of arsenic (N. N. R.), was first synthesized by Ehrlich and later in 1921 by Tréufouel and Fourneau. Reports have appeared on the favorable use of the drug in amebiasis, but they are conflicting as to its therapeutic efficiency and toxicity. Experimentally, Anderson and Leake (*Proc. Soc. Exper. Biol. & Med.* **27:**267 [Jan.] 1930) showed that acetarsone is approximately four times as toxic as originally noted by Levaditi, when administered orally to rabbits and cats. Clinical cases of poisoning are not uncommon, even when therapeutic amounts of the drug are used (Michael, J. C.: THE JOURNAL, Feb. 23, 1929, p. 645. Bender: *Am. J. M. Sc.* **174:**819 [Dec.] 1927). New and Nonofficial Remedies (1931) states that "the physician should remember that he is working with a rather toxic arsenical preparation, which may give rise to gastro-intestinal symptoms, as well as to the same cutaneous disturbances that are found with the arsphenamines, for example, urticaria, erythema of various types and even hemorrhagic eruptions. At the least sign of intolerance the physician should discontinue the use of the drug for the time being." The recommended total adult dosage is 5 Gm. given orally over a seven to ten day period.

There seems to be no doubt that other amebacides, arsenical and nonarsenical, are available which have equal and greater amebacidal action and are less toxic than acetarsone.

ARGYROSIS OF EYELID

To the Editor:—Kindly give treatment for argyrosis of the lower lid, caused by the injection of a silver solution into the tissue fifteen or eighteen years ago. Please omit name.

M.D., Washington.

ANSWER.—Stillians and Lawless (*Arch. Dermat. & Syph.* **17:**153 [Feb.] 1928) described a method for the removal of the bluish discoloration of argyria. A mixture containing 0.25 per cent potassium ferrocyanide and 6 per cent sodium thiosulphate is injected intracutaneously into the area of argyria. This produces a wheal, followed by an erythema. The latter subsides within a few days, leaving a clear area slightly smaller than the wheal produced by the injection. A platinum needle should be employed, and the two chemicals should not be combined until just before using.

PAIN IN SCAR AFTER OPERATION

To the Editor:—I have a patient who had a cholecystectomy performed about three months ago; she has complained since the operation of a constant burning pain in the upper two inches of the incision; the scar has a beefy red color, and the pain extends about three inches to the right of the upper end of the scar; the area is very tender and clothing seems to irritate it. Movement of the right arm seems to increase the pain. Please advise as to diagnosis and treatment. Please omit name.

M.D., Missouri.

ANSWER.—The type of scar described occasionally occurs in wounds that have been drained and in patients in whom there is a tendency to keloid formation. In either event, the excess of scar tissue is probably a factor. Sensitiveness or tenderness and paresthesias in such scars usually subside within a few weeks. In some instances in which such discomfort has persisted without obvious reasons, neurologists have been inclined to diagnose the cause as mental and to treat it accordingly. Fixation of a layer or two of gauze to prevent contact with the clothing may be tried Such local remedial measures as the application of heat and light massage are of value Occasional injection of a small amount of 0 5 per cent procaine hydrochloride solution has been used with benefit Actual keloid should be irradiated

TREATMENT OF SEVERE OBESITY

To the Editor —I have a patient aged 37 years, weighing 470 pounds (213 Kg), blood pressure 110 systolic and 70 diastolic, blood Wassermann negative, who has been gaining weight from 180 pounds (81 6 Kg) to the present weight from about six years ago The patient has been taking large doses of thyroid with 2 grains (0 13 Gm) of ovarian substance every day for the past three years and has continued to gain weight I am particularly anxious to have information concerning intravenous and intramuscular injections in a case of this type

Paul B Shuey, M D, Long Island City, N Y

Answer —In the question, not a word is said about the diet Unless the patient is willing to diet and diet strenuously, no amount of any endocrine substances will reduce the weight No one has ever shown that thyroid works better given with a needle than it does when given by mouth Ovarian extract is generally held to be efficacious only if given hypodermically, but it is doubted that it would have any effect on the obesity Certainly emphasis must be placed on a subcaloric diet

PRESCRIPTION OF IRON AND AMMONIUM CITRATE

To the Editor —Literature at my command does not give me adequate information on the best method of administering iron citrate or iron and ammonium citrate Is the large dose advised? I would like this information for dispensing rather than for prescribing

A L Brankami, M D, Banning, Calif

Answer —Iron and ammonium citrate is readily soluble and may be pleasantly administered in liquid dosage form dissolved in the aqueous elixir of glycyrrhiza, N F, as in the following prescription

	Gm or Cc
℞ *Iron and ammonium citrate*	10
Aqueous elixir of glycyrrhiza	120

M Label Teaspoonful in water three times a day after meals

A teaspoonful of this preparation contains approximately 0 3 Gm of the iron salt The large dose, about 1 Gm, which is probably more efficient, would be secured by giving a tablespoonful of this solution

Iron citrate, which is rather insoluble, could be administered in capsule form

MYCOSIS FUNGOIDES

To the Editor —A man, aged 53, was injured by a crushing blow in the pelvic region For some time he complained of pain in this region, and some months later an eruption began at the site of the lesion and gradually spread over the body The diagnosis was mycosis fungoides Would it be possible for the injury to be the exciting cause of the mycosis?

Robert J Sagerson, M D, Johnstown, Pa

Answer —It is conceivable that the lowering of resistance due to injury might precipitate mycosis fungoides There is one reference to such an occurrence

McNeil, Murray and Atkinson *Glasgow Hosp Rep* 1 53, 1898

NUTRITIVE EFFECTS OF NEAR BEER

To the Editor —Is it possible to derive the same nutritive properties as to vitamin and caloric content from near beer as from alcoholic beer? What do you think of moderate quantities of beer as a fattening agent? Please omit name

M D, California

Answer —The vitamin properties of beer are contained in the yeast and yeast derivatives These are present in near beer as well as in alcoholic beer The use of beer, even in moderate quantities, may promote a gain in weight

MORPHINE IN OPERATIONS ON RESPIRATORY TRACT

To the Editor —Is morphine sulphate contraindicated in tracheal or laryngeal operations under general anesthesia?

P J Cradey, M D, Chicago

Answer —Owing to the fact that morphine depresses the respiratory centers, many laryngologists do not employ it in case of tracheal or laryngeal operations under general anesthesia In many of these cases there is already a potential if not an actual anesthesia, so that the use of morphine would simply be adding another hindrance to the operation

Council on Medical Education and Hospitals

COMING EXAMINATIONS

American Board for Ophthalmic Examinations Montreal, Sept 19 Sec, *Dr William H Wilder, 122 S Michigan Ave*, Chicago

American Board of Obstetrics and Gynecology The examination will be held in nineteen different cities in the United States and Canada, Oct 22 Sec, Dr *Paul Titus 1015 Highland Bldg*, Pittsburgh

American Board of Otolaryngology Montreal, Sept 17 Sec, Dr W P Wherry, 1500 Medical Arts Bldg, Omaha

Arizona *Phoenix*, Oct 3 Acting Sec, Dr Jos M Greer, Professional Bldg Phoenix

Book Notices

Physiotherapy: Its Principles and Practice. By F. Howard Humphris, M.D., F.R.C.P., M.R.C.S., Hon. Consulting X-Ray Physician and Electrotherapist to Christ's Hospital, and Ralph E. Stuart-Webb, M.B., B.S., M.R.C.S. With contributions by Frank Romer, M.R.C.S., L.R.C.P., A. E. Hayward Pinch, F.R.C.S., M.R.C.P., and A. Gordon Watson, M.D. Cloth. Price, $4.50. Pp. 399, with 74 illustrations. New York: Macmillan Company, 1932.

Probably the most significant lesson to be derived from the reading of this book is the realization of the great variety of methods utilized in physical therapy and the overlapping of effects obtained by their employment. The entire category of agencies and technics now practiced as physical therapy is discussed, but, owing to the limited space devoted to each subject, only the most cursory impressions are left with the reader. From a practical point of view the book offers little more than an extensive propaganda in favor of this discipline. As a contribution to the subject it fails to add to the knowledge that is already at hand, contributed both by the earlier publications of Humphris and by the publications of contemporary writers in this field of practice. It is deficient in necessary detail because it has emphasized the broadest concepts of its clinical practice. The large canvas on which the authors have attempted to give outline to their subject is presented in optimistic colors, but the presentation is as unconvincing as are the modernistic sketchings of futuristic art. The novice will perhaps close the final page with a considerable degree of confusion, because it is doubtful whether he will be able by himself to employ a single physical agency from the generalized statements found in the text. At best, and perhaps this was the main purpose of the authors, the reader will obtain from its perusal a stimulus to orient himself in greater detail with this practice by reading the more concise works now at hand in medical literature. To the practitioner already oriented in the subject, the book will have no greater importance than another affirmation. The impression of the critical reader is that the work is the result of energy questionably expended. It has added nothing new and is but a regurgitation of information already well known or, in some instances, still in the realm of conjecture. The glossary will be found of practical value. It is concise in its definitions but not exhaustive in range. The book has that irritating quality of suggesting a wealth of therapeutic possibilities presented in such a generalized manner as to make it impossible to adapt the procedures for personal use.

Entstehung, Erkennung und Behandlung innerer Krankheiten. Von Dr. Ludolf Krehl, Professor in Heidelberg. Band II: Die Erkennung innerer Krankheiten. Von Dr. Ludolf Krehl. Second edition. Paper. Price, 12.80 marks. Pp. 197. Berlin: F. C. W. Vogel, 1932.

It is evident from the publication of a second edition one year after the first (reviewed in these columns, June 18) that this book on the principles of diagnosis in internal medicine was promptly welcome by the profession. The new edition is an expansion, not a retraction. The original text, save for a few small omissions, has been preserved, a sentence or two being added as an ending to a paragraph or for greater clarity or repeated insistence. Many new paragraphs supply information the author admits he forgot when he wrote the book; others pertain to matters of which he failed to realize the importance at the time; some are incidental to recent progress. To the criticism that he failed in the first edition to consider properly some modern tests for the function of certain organs, Professor Krehl replies that he does not believe they are as valuable as their authors say they are; that a great deal needs to be learned about the malfunctioning for which certain methods of detection have been prescribed. He maintains emphatically that diagnosis is promoted by numerous exact chemical procedures, that this ground should be plowed and sown more than ever before, in spite of the frequent harvests of more stone than bread. He insists that as many as possible of the refined steps for accurate diagnosis should be carried out by the attending physician; that thereby the standing of the physician is enhanced and the expense of the patient lessened; that no measures of value in making a diagnosis should be omitted; that when outside help is necessary, careful judgment should determine both its amount and its source.

Among new statements more directly applicable to special diagnosis are references to the difficulty in recognizing hemorrhagic diseases when surfaces and joints are not particularly involved, to the likelihood of thinking some of the lymph glands are tuberculous early in leukemia when only a few are enlarged; the occurrence of essential thrombopenia in acute as well as chronic, and in both severe and mild, forms; the recognition, at times, of Vaquez's disease almost at a glance by the ruddy hue of the patient and its adaptive development compensating for cardiac or for pulmonary disease. When the disease is primary, the spleen is enlarged and blood pressure may be increased. A paragraph in the first edition (p. 64) in which are discussed the relations of small arteries generally, their smooth muscle and innervation to pulmonary edema has been omitted. In its place, dyspnea from sclerosis of the arteries of the respiratory centers is contrasted with that from heart disease. Attention is called to sequences of influenza caused by disturbances in the vegetative nervous system and lasting many months; to the possibility of, and ways of recognizing, meningitis and encephalitis when infectious diseases beginning tempestuously possess such complications; to the existence of nephritis before it becomes outspoken. Efforts should be made to detect vascular disease when nephritis has been demonstrated. As for the term "nephrosis," Krehl says that he has found no occasion to employ it. He believes that the interrelation of physical and mental states in patients with rheumatism is important, recalling that rheumatism is conspicuous in the arena of quackery. Although others have observed a wide variety of pains with hypertension, he has not noted such symptoms especially. Changes in joints caused by inflammation, he believes, should be differentiated sharply from those due to degeneration. The two types of disease are often so interlaced, especially when they are chronic, that it is not easy to decide just what dominates. But the retrogressive changes belong to arthritis deformans, whereas the inflammations suggest infection.

Krehl believes that modern conceptions have reduced the usefulness of subdividing aphasia into various forms, as has long been the practice of many writers, and recommends a thorough understanding of the nature of speech and of its associated mental activities. Also important in this connection is knowledge of the general condition of the brain in patients with aphasia. A circumstantial description of the differences between nervous cardiac disturbances and those due to organic disease has been introduced. Long clinical experience has taught the author that neurotic patients with functional heart symptoms are actually ill and that some of them may suffer at the same time from a complicating structural heart disease. Among the many expedients for learning the condition of hepatic functions, he has found tests with dextrose and galactose useful; for pancreatic functioning, he examines the blood and urine for diastase. When jaundice is present, the possibility of a syphilitic infection should be investigated and tests for hemolysis made. In the chapter on digestion, a short account of the tongue in disease has been inserted. It was overlooked in the first edition. By such statements and by many others of less significance the book has been improved and enlarged, the latter contributed to by a change to uniform type, so that the pages are increased by twenty-five. As in the first volume, "Physiologische Physiologie," references to investigations in countries other than Germany are relatively few. With publication of the third volume, "Behandlung," there will be available a complete modern work on internal medicine of an unusual type in which the customary ritualistic description is replaced by interpretation of principles.

Male Disorders of Sex. By Kenneth M. Walker, F.R.C.S., Lecturer in Venereal Diseases to St. Bartholomew's Hospital. Cloth. Price, $2. Pp. 191. New York: W. W. Norton & Company, Inc., [n. d.]

This volume is devoted largely to a consideration of the mechanism of sex life and to the causes and treatment of impotence. The author also considers homosexuality, masturbation, priapism and continence. The second part of the book is concerned with sterility and its treatment. The volume is small but highly concentrated. It really tells all that a general practitioner needs to know about the subjects it discusses. The chapters dealing with the available surgical procedures are sufficiently conservative and do not promise much that cannot be delivered.

Cancer: Civilization: Degeneration. The Nature, Causes and Prevention of Cancer, Especially in Its Relation to Civilization and Degeneration. By John Cope. Cloth. Price, 15/-. Pp. 293, with 53 illustrations. London: H. K. Lewis & Company, Ltd., 1932.

This is another of the too numerous speculative treatises on cancer. It is based on the assumption that primitive people and earlier civilizations were relatively free from this disease, and that cancer depends largely on social conditions and personal habits. The argument wanders through the fields of sociology, economics and politics, with particularly unfavorable comments on British politics and international relationships as being part of the picture of social decadence that is at the bottom of the occurrence of cancer in the British Isles. The arguments are reinforced by illustrations from *Punch* and quotations from sacred and profane writers. A fair idea of the significance of the work can be obtained from the following statement from the concluding chapter: "Cancer is a painful disease inflicted upon us by a beneficent spirit or 'nature' for the purpose of warning us against the commission of some breach of law. That the fault is a heinous fault, the sin a deadly sin, may be gathered from the severity of the punishment. The place and quality of the cancer also furnish us with clues as to the kind of sin being committed. Nature fits the punishment to the crime. Our implicit faith in the beneficence of the Creator or of Nature assures us that this terrible visitation, whereby the nation is worse than decimated, is due to our own wrongdoing. We know that in order to deserve so hideous and so extensive a punishment the fault must be both serious and widespread—of national as well as of individual significance. Our study of the causes and nature of cancer enables us to state that our offense is that of idleness —of not using certain organs to an extent which shall maintain their efficiency. It signifies that we have disregarded the edict that fitness can be secured only by effort: that in nature it is the fit and not the unfit which win in the race." On this material is wasted an excellent piece of book making, worthy of a better cause.

Case for Mr. Fortune. By H. C. Bailey. Cloth. Price, $2. Pp. 308. Garden City: Doubleday, Doran & Company, Inc. Published for the Crime Club, Inc., 1932.

This new accumulation of detective stories continues the quality set by the author in previous volumes. Mr. Fortune is a medical detective with a great deal of common sense and sound philosophy. Most volumes of mystery and detection are written by writers with a flair for plot but without much literary skill. Mr. Bailey reveals not only everything desirable in the way of plot but a literateness that makes him worth while even for the most intelligent reader.

Traité d'anatomie humaine. Par P. Poirier et A. Charpy. Sous la direction de A. Nicolas, *professeur honoraire d'anatomie à la Faculté de médecine de Paris.* Avec la collaboration de MM. O. Amoëdo, Argaud, et al. Tome I: Premier fascicule (première division): Introduction, par L. Manouvrier. Anatomie générale, par J. Verne. Développement des os, par J. Verne. Constitution générale du squelette, par M. Augier. Squelette céphalique, par M. Augier. Fourth edition. Paper. Price, 130 francs. Pp. 667, with 393 illustrations. Paris: Masson & Cie, 1931.

The appearance of the fourth edition of this work is a matter of great interest to anatomists, physicians, surgeons and students the world over. They have learned to regard the book as a valuable and reliable storehouse of information. The first edition was published in five volumes, the first of which appeared in 1892. Three parts of the fourth edition have already appeared, a section on angiology, another on arthrology, and now this, which is the first section of the first volume and which, after the introduction and brief chapter on general anatomy, is devoted to the skeleton of the head. Sections devoted to the lymphatics and to the skeleton of the thorax, vertebral column and limbs are in preparation. This section is largely the work of Augier. It has been entirely recast and considerably enlarged, containing 566 pages as compared with 203 in the third edition, and 313 illustrations as compared with 197. As the section on general anatomy and an introduction fill 88 pages, it constitutes altogether a volume of 667 pages. The excellent qualities of previous editions are retained, and there are added sections on the skeleton of the head taken as a whole, devoted to general configuration, asymmetry, sutures, structure and physical qualities, growth, changes with age and senility, differences in the sexes, craniometry and its applications, and variations and malformations due to abnormal conditions existing either in the bone itself or in the brain. A valuable innovation is an index. The extensive bibliographic list which characterized previous editions is brought in this one down to 1928, although the enormous list of papers that have appeared in recent years has made it impossible to include all of them. The new edition cannot fail to be of great service because there is evident in it the excellent organization and the clearness of statement which have always characterized this, the most complete of French works on anatomy.

Artériographie des membres et de l'aorte abdominale. Par Reynaldo dos Santos, professeur à la Faculté de médecine de Lisbonne, A. C. Lamas, chirurgien des Hôpitaux de Lisbonne, et J. P. Caldas, radiologue des Hôpitaux de Lisbonne. Préface du Professeur Leriche. Paper. Price, 45 francs. Pp. 192, with 54 illustrations. Paris: Masson & Cie, 1931.

This is a record of the work done by dos Santos and other Portuguese surgeons in attempts to study the condition of arteries in living patients. They have followed methods that were introduced by Dr. Barney Brooks in this country ten years ago and which have been applied by other surgeons of America and of Europe ever since. The Portuguese surgeons have ventured daringly to extend these methods to a study of the abdominal aorta and of the arteries of the brain. They have injected sodium iodide and other organic salts of iodine directly into the aorta through needles 12 cm. long and 0.9 mm. in diameter, introduced obliquely from the back and made to pierce the aortic wall. Through these needles they injected, with the help of a mechanical apparatus, solutions of sodium iodide in amounts up to 45 Gm., and by means of roentgenograms made in the few seconds immediately following the injection have suceeded in showing up, with astonishing clearness and completeness, the blood vessels of the abdomen and of all its viscera. The pressure apparatus utilized enables them to control the amount injected and the speed of its delivery into the circulating blood. They have applied similar methods to the study of arteries in the brain and in the limbs. The book contains reproductions of the roentgenograms thus obtained. Dos Santos states that he has made more than 300 injections into the aorta and that he has seen no accidents or complications which would confirm the fears of surgeons who hesitate to adopt such daring and apparently dangerous procedures. Among the advantages accruing from this method of direct observation of arteries are that it permits the exact observation of abdominal aneurysms or vascular obstructions, the differential diagnosis of tumors of the left hypochondrium, the demonstration of abnormal vessels in hydronephroses, and observations of the condition of the circulation in the early stages of many diseases in which changes in the blood vessels and in the modalities of their working are important factors. An enthusiastic introduction is contributed by René Leriche of Strasbourg, pointing to the many ways in which this method may be useful in the future. There is also a brief historical account of work along similar lines. The accounts of technical methods are brief but definite and clear. An appendix added after the main part of the book had already gone to press advocates the utilization of some new compounds of thorium which promise to be both less toxic and less painful than sodium iodide and at the same time sufficiently opaque. The author commends also the utilization of an iopax derivative which has given excellent results.

The Expectant Mother's Handbook. By Frederick C. Irving, A.B., M.D., Professor of Obstetrics, Harvard Medical School. Cloth. Price, $1.75. Pp. 203, with 26 illustrations. Boston: Houghton Mifflin Company, 1932.

This book, written by a leading obstetrician, answers in a satisfactory and lucid manner questions which prospective mothers usually ask. In writing this book the author had two objects in mind. The first was to acquaint women with the facts of pregnancy and labor and the second was to dispel certain untruths and superstitions concerning these physiologic processes. The author has succeeded admirably in his task and hence the book can be highly recommended to expectant mothers. It is unfortunate that the author speaks of a final examination in the light in which it is considered by most physicians today. He should emphasize the fact that an examination made six or eight weeks after confinement and usually designated as the final examination should not be looked on as the final contact between physician and patient until a new pregnancy supervenes. Women should be urged to see their physicians not only six weeks after a baby is born but at least once more before the child is a year old and at least once a year thereafter. These examinations are most important to prevent morbidity, especially cancer.

De mensch en zijn marine verleden: Een theorie over de functie en de pathologie der tonsillen, en tevens een aanwijzing omtrent een mogelijke betrekking daarvan tot de endocrine- en speekselklieren. Door Dr. C. A. J. Quant, Arts te Diepenheim. Paper. Price, 1 guilder. Pp. 39. Haarlem: De Erven F. Bohn, n. v., 1932.

The author has appended a summary of this article in rather quaint English. The title of the summary is "On Tonsils and Adenoids, a Theory of Their Origin, Their Function and Their Pathology, and Their Possible Relation to the Salival and Endocrine Glands." The author is endeavoring to determine the actual significance of the lymphatic ring of Waldeyer. He has studied the comparative anatomy of the gills and their function in fishes, endeavoring to find in evolution more explanation regarding the function of the upper portion of the throat. The author assumes there is a certain excretive function connected with the adenoids. There is also a relation between this function and that of the salivary glands. He considers there is a parallelism between the action of the iodine in the sea water and the iron in the lungs, both acting as catalytic agents. The author compares the different parts of the ring of Waldeyer with various portions of the so-called ring of endocrine glands, such as the thyroid, hypophysis and parathyroid. It is unfortunate that the translation is not accurate, so that it is difficult to get a correct idea of the hypothetical propositions advanced by the author.

Medicolegal

Hospital's Liability for Safety of Delirious Patient

(Maki v. Murray Hospital (Mont.), 7 P. (2d) 228)

Maki sued the Murray Hospital and a member of its medical staff, for injuries sustained while a patient in the hospital. He was admitted to the hospital for treatment for erysipelas. He alleged that he became delirious and that the defendants negligently permitted him to fall from the third floor of the hospital building. The trial court directed a verdict in favor of the defendant-physician and charged the jury that the plaintiff must prove negligence on the part of the hospital by a preponderance of evidence, that the law presumes that the hospital was not guilty of negligence, and that the mere fact that the plaintiff was injured does not of itself create any presumption or inference of negligence on the part of a hospital. The jury returned a verdict for the hospital. Subsequently, the trial court concluded it had erroneously instructed the jury and granted the plaintiff a new trial. The hospital appealed to the Supreme Court of Montana, where the action of the trial court, granting a new trial, was affirmed.

The plaintiff was admitted to the hospital, March 20. On the morning of March 23, while the nurse in charge was in the bathroom washing up the dishes from the plaintiff's breakfast tray, a painter mounted a scaffold in the hall and peered through the plaintiff's transom. The plaintiff becoming violently delirious, sprang from his bed, rushed into the bathroom, and told the nurse that a man was coming through the transom to shoot him. The nurse tried to quiet the patient and at the same time tried to restrain him. He struck her, broke from restraint, and jumped from the window. It is apparent, said the Supreme Court, from the record that the plaintiff had no knowledge in what manner he received his injury, or in what manner the defendant hospital was negligent in permitting him to become injured. He knew, however, as an ordinary reasoning being, that an unconscious patient in a hospital would not ordinarily receive such injuries unless those to whose care he had been committed were negligent. While it is necessary, continued the court, in every personal injury action to prove negligence, courts generally recognize the fact that persons are often injured under circumstances where it would be impossible to prove the facts showing negligence, and yet, by common knowledge and experience, it is clear that such injury would not have been sustained had the responsible party not been negligent. In such cases the doctrine of res ipsa loquitur is applicable. While the doctrine is usually applied where the injury is occasioned by machinery and instrumentalities under the exclusive control and operation of the defendant, the doctrine should apply, in the opinion of the court, with equal force in cases wherein medical and nursing staffs take the place of machinery and may, through carelessness or lack of skill, inflict, or permit the infliction of, injury on a patient who is thereafter in no position to say how he received his injury. This doctrine applies in the present case, said the court, and unless the hospital explained away the presumed negligence, the plaintiff is entitled to recover, and the jury should have been so instructed.

A hospital conducted for profit is not an insurer of patients against self-inflicted injuries but it is required to use ordinary and reasonable care and diligence in their treatment. A patient is entitled to such reasonable care and attention for his safety as his mental and physical condition may require. The degree of such care should be in proportion to the physical and mental ailments of the patient rendering him unable to look after his own safety. It is the duty of a hospital to use reasonable care to employ only competent physicians and nurses. Those who by reason of affliction place themselves in the hands of the medical and nursing staffs of a hospital, and agree adequately to compensate the hospital for the care and attention required by their mental and physical condition, have a right to rely on the performance of such duties. A hospital cannot exculpate itself merely by showing that those in charge of the patient did not know the conditions existing, regardless of what they should have known. The question of whether or not the explanation on the part of the hospital as to the circumstances under which the plaintiff received his injury was sufficient to overcome the prima facie case resulting from the application of the doctrine of res ipsa loquitur, said the court, was clearly a jury question, under proper instruction from the court.

Workmen's Compensation Acts: Weight to Be Attached to Opinions of Attending Physician.—On May 14, 1931, in the course of McReynolds' employment, a splinter 1½ inches long was accidentally embedded in his arm, just above the elbow. Infection followed. He recovered sufficiently to be able to return to work, but he was unable to discharge fully his duties as shop foreman. There were red streaks radiating up and down the arm from the wound, for several inches, and the presence of a lump indicated the development of pus at the site of the wound. The wound was lanced on or about June 1, after which it appeared to heal, although McReynolds continued to complain of pain in the arm. On June 5, pneumonia developed suddenly, accompanied by a low leukocyte count. Death occurred, June 12. McReynolds' widow claimed compensation under the workmen's compensation act. The two physicians who attended McReynolds during his last illness testified that the wound did not cause the pneumonia from which he died, but one of them was extremely hesitant about committing himself concerning the matter. The workmen's compensation commissioner who heard the cause appointed three disinterested physicians and propounded to them a hypothetical question that described the circumstances under which McReynolds was injured, the symptoms from which he suffered, and his death, and asked what in the several opinions of these witnesses caused the pneumonia that resulted fatally. They answered that death resulted from septic pneumonia, probably due to the injury. The Industrial Commission then made an award in favor of the widow, from which the employer and the employer's insurer appealed. The general rule, said the Supreme Court of Appeals of Virginia, is that when an attending physician is positive in his diagnosis of a disease, great weight will be given by the courts to his opinion. However, when it appears, as we think it does in this case, that the diagnosis is shaded by doubt, and there is medical expert opinion contrary to the opinion of the attending physician, then whoever is judge of the facts is left free to adopt that view which is most consistent with reason and justice. The Industrial Commission, the trier of the facts in this case, was of the opinion that the preponderance of evidence showed that the deceased died of septic pneumonia, caused by infection from the wound. In that conclusion, the Supreme Court of Appeals concurred. The award in favor of the widow was therefore affirmed.—*Bristol Builders' Supply Co., Inc., v. McReynolds (Va.), 162 S. E. 8.*

Insanity: Annulment of Marriage.—To render a marriage invalid because of insanity on the part of one of the parties to the marriage contract, it must be shown clearly and convincingly that at the time of the marriage the alleged incompetent party was unable to understand the nature of the contract of marriage and to appreciate the legal consequences naturally deducible therefrom. Every variation from a normal mental condition is not in itself enough to void the marriage contract. The mental defect or derangement must be one having a direct bearing on such contract. Mere weakness and imbecility of mind is not sufficient, nor eccentricity nor partial dementia, but it must be such a general mental derangement as prevents the party from comprehending the nature of the contract of marriage and from giving to it his free and intelligent consent. If the party entering the marriage relation has sufficient capacity to understand the nature of the contract and the duties and responsibilities which it creates, the marriage will be valid.—*Elfont v. Elfont (Md.), 157 A. 741.*

Health Insurance: Treatment by Mail as "Regular Treatment by a Physician."—A health insurance policy provided that certain benefits would be paid if the insured "shall be totally disabled from performing his or her duties, although not confined in the house, but receiving regular treatments from the physician at least once each seven days." The insured apparently became totally disabled and was under the care of a physician. On his advice, she went to her father's home in a nearby town. Thereafter she was treated by him at least once a week, either at his office or by mail. It was contended that this did not constitute "regular treatment by a physician." Treatment by sending medicine or prescriptions through the mail, said the Supreme Court of Arkansas, constitutes regular treatment by a physician within the meaning of the insurance policy.—*Inter-Ocean Casualty Co. v. Huddleston (Ark.), 45 S. W. (2d) 21.*

Workmen's Compensation Acts: Liability of Employer for Medical Treatment in the Absence of Request Therefor.—Under the Oklahoma workmen's compensation act, an employer and his insurance carrier are not liable for medical expenses incurred by an injured employee, if the employee does not request medical treatment from them, gives them no notice of his need for medical treatment and they have no knowledge of that need.—*Summit Drilling Co. v. Graham (Okla.), 6 P. (2d), 693.*

Charitable Hospitals: Liability for Negligence of Nurse.—A charitable hospital is not liable in damages to a pay patient for injury due to the negligence of a nurse in administering to that patient medicine intended for another, provided the hospital has exercised ordinary care in the selection and retention of the nurse.—*Enell v. Baptist Hospital (Texas), 15 S. W. (2d) 395.*

Society Proceedings

COMING MEETINGS

American Academy of Ophthalmology and Otolaryngology, Montreal, Sept. 19-23. Dr. William P. Wherry, 1500 Medical Arts Building, Omaha, Neb., Executive Secretary.

American Association of Obstetricians, Gynecologists and Abdominal Surgeons, French Lick, Indiana, Sept. 12-14. Dr. Magnus A. Tate, 19 West Seventh Street, Cincinnati, Secretary.

American College of Surgeons, St. Louis, October 17-21. Dr. Franklin H. Martin, 40 East Erie Street, Chicago, Director General.

American Congress of Physical Therapy, New York, Sept. 6-10. Dr. J. B. Bulmer, 185 North Wabash Avenue, Chicago, Secretary.

American Hospital Association, Detroit, Sept. 12-16. Dr. Bert W. Caldwell, 18 East Division Street, Chicago, Executive Secretary.

American Physical Therapy Association, Detroit, September 28-30. Dr. C. C. Vinton, 211-02 S. Conduit Blvd., Rosedale, N. Y., Secretary.

American Public Health Association, Washington, D. C., October 24-27. Dr. Kendall Emerson, 450 Seventh Avenue, New York, Acting Executive Secretary.

American Roentgen Ray Society, Detroit, September 27-30. Dr. Eugene P. Pendergrass, 3400 Spruce Street, Philadelphia, Secretary.

Associated Anesthetists of the United States and Canada, New York, October 17-21. Dr. F. H. McMechan, 318 Hotel Westlake, Rocky River, Ohio, Secretary.

Association of Military Surgeons of the United States, Hartford, Conn., October 20-22. Dr. J. R. Kean, Army Medical Museum, Washington, D. C., Secretary.

Central Association of Obstetricians and Gynecologists, Memphis, Tenn., September 15-17. Dr. E. D. Plass, University Hospital, Iowa City, Secretary.

Colorado State Medical Society, Estes Park, Sept. 8-10. Mr. Harvey T. Sethman, 227 16th Street, Denver, Executive Secretary.

Delaware, Medical Society of, Lewes, September 27-28. Dr. W. O. La Motte, 604 Medical Arts Building, Wilmington, Secretary.

Idaho State Medical Association, Pocatello, Sept. 16-17. Dr. Harold W. Stone, 105 North Eighth Street, Boise, Secretary.

Indiana State Medical Association, Michigan City, September 27-29. Mr. T. A. Hendricks, 23 East Ohio Street, Indianapolis, Executive Secretary.

Inter-State Postgraduate Medical Association of North America, Indianapolis, October 24-28. Dr. W. B. Peck, 12½ East Stephenson Street, Freeport, Ill., Managing Director.

Kentucky State Medical Association, Louisville, October 3-6. Dr. A. T. McCormack, 532 West Main Street, Louisville, Secretary.

Michigan State Medical Society, Kalamazoo, Sept. 13-15. Dr. F. C. Warnshuis, 148 Monroe Avenue, Grand Rapids, Secretary.

Nevada State Medical Association, Reno, Sept. 23-24. Dr. Horace J. Brown, 120 North Virginia Street, Reno, Secretary.

Northern Minnesota Medical Association, Crookston, Sept. 19-20. Dr. O. O. Larsen, Detroit Lakes, Secretary.

Oregon State Medical Society, Klamath Falls, Sept. 22-24. Dr. Albert W. Holman, 410 Taylor Street, Portland, Secretary.

Pennsylvania, Medical Society of the State of, Pittsburgh, October 3-6. Dr. Walter F. Donaldson, 500 Penn Avenue, Pittsburgh, Secretary.

Southern Minnesota Medical Association, Rochester, Sept. 12. Dr. M. C. Piper, Mayo Clinic, Rochester, Secretary.

Utah State Medical Association, Ogden, Sept. 15-17. Dr. Leland R. Cowan, 305 Medical Arts Building, Salt Lake City, Secretary.

Vermont State Medical Society, Burlington, October 6-7. Dr. William G. Ricker, 31 Main Street, St. Johnsbury, Secretary.

Washington State Medical Association, Tacoma, Sept. 12-14. Dr. Curtis H. Thomson, 1305 Fourth Avenue, Seattle, Secretary.

Wisconsin, State Medical Society of, Milwaukee, Sept. 14-16. Mr. J. G. Crownhart, 119 East Washington Avenue, Madison, Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Issues of periodicals are kept on file for a period of five years only. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending, but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

American Heart Journal, St. Louis

7: 553-694 (June) 1932

*Apical Systolic Murmurs in Children: Follow-Up Observations in One Hundred Cases. M. H. Fineberg and L. G. Steuer, Cleveland.—p. 553.
Roentgenographic Studies of Right Ventricle. G. Nemet and J. B. Schwedel, New York.—p. 560.
Functional Longitudinal Block in Human Heart: Probable Case with Unusual Arhythmia. W. J. Kerr and J. J. Sampson, San Francisco.—p. 574.
*Status Angiosus Induced by Paroxysmal Auricular Fibrillation and Paroxysmal Tachycardia. P. D. White and P. D. Camp, Boston.—p. 581.
*Treatment of Spasmodic Vascular Disease of Extremities of Raynaud Type. Alice R. Bernheim and Isabel M. London, New York.—p. 588.
Ventricular Bigeminy (Parasystole or Reciprocal Rhythm) in Atrioventricular Rhythm. D. Luten and J. Jensen, St. Louis.—p. 593.
Study of Gallop Rhythm by Combination of Phonocardiographic and Electrocardiographic Methods. P. Duchosal, Geneva, Switzerland.—p. 613.
Localization of Experimental Ventricular Myocardial Lesions by Electrocardiogram. J. H. Crawford, G. H. Roberts, D. I. Abramson and J. C. Cardwell, Brooklyn.—p. 627.
Coarctation of Aorta (Adult Type): Report of Three Cases. H. L. Ulrich, Minneapolis.—p. 641.
*Action of Adrenalin on Patients with Complete Heart Block and Stokes-Adams Seizures: Comparison of Effects of the Drug on Patients with Syncopal Attacks Due to Standstill of Ventricles and Those Due to Ventricular Fibrillation. S. P. Schwartz and A. Jezer, New York.—p. 652.
Auriculoventricular Nodal Paroxysmal Tachycardia and Auricular Flutter: Case Report. F. B. Carr, Worcester, Mass.—p. 668.

Apical Systolic Murmurs in Children.—A follow-up study, covering an average period of six years, was made by Fineberg and Steuer of 100 children with uncomplicated apical systolic murmurs, with the following results: Serious complications (mitral stenosis, aortic insufficiency or both) developed in 30 per cent of all the patients. Serious cardiac complications developed in 50 per cent of those giving a history of rheumatic fever or chorea. Serious cardiac manifestations developed in 37 per cent of those showing clinical enlargement at the first examination. Serious cardiac manifestations developed in 40 per cent of those showing enlargement by orthodiagram. Further evidences of cardiac disease developed in only 9 per cent of those giving entirely normal fluoroscopic observations. Only 8 per cent of the patients showed complete disappearance of the murmur. Only one of the seven patients 5 years of age or under presented serious cardiac complications and this patient had an attack of chorea at 8 years of age, following which mitral stenosis developed. The electrocardiogram seemed to be of no value in estimating the prognosis.

Status Anginosus Induced by Paroxysmal Auricular Fibrillation and Paroxysmal Tachycardia.—White and Camp report four unusual but important cases to illustrate the fact that a status anginosus may occur without coronary thrombosis. A great increase in heart rate due to paroxysmal auricular fibrillation or paroxysmal tachycardia (with accompanying drop in systolic blood pressure or pulse pressure) was evidently responsible for the induction of the angina pectoris that was at other times a characteristic result of effort in all of these four cases. Two of the patients were men, aged 62 and 66, and two were women, aged 68 and 75. One of the men (the first) and one of the women (the second) died suddenly eighteen months and fifteen months, respectively, after the first attack of angina pectoris induced by the abnormal heart rhythm. The other two patients were alive one year after their first attacks of this nature.

Treatment of Spasmodic Vascular Disease.—Bernheim and London describe four cases in which there was spasmodic vascular disease of the Raynaud type characterized by hypersensitiveness to cold. Distinct benefit was obtained by a high-calcium and high-vitamin regimen. The authors call attention to the fact that the effect of calcium differs from that of sympathectomy in that no permanent alteration of the vasomotor nervous mechanism is brought about.

Action of Epinephrine on Heart Block.—Schwartz and Jezer gave epinephrine in varying dosages to four patients who had complete auriculoventricular dissociation and who were subject to syncopal seizures. In two of the patients the syncopal attacks were due to a slowing of the ventricular rate, while in the other two they were associated with transient periods of ventricular fibrillation. The same dose of epinephrine was found to act variably at different times in the same patient when administered either subcutaneously or intramuscularly. Epinephrine was found to increase both the auricular and the ventricular rates of the patients in whom the syncopal seizures were due to standstill of the ventricles. The increases in these rates were observed both preceding and during the Stokes-Adams attacks and were both regular and irregular in rhythm. The drug produced its effects primarily through a direct stimulation of the idioventricular pacemaker. Epinephrine induced short periods of transient ventricular fibrillation with syncope in two patients in whom the Stokes-Adams attacks were found to be due to ventricular fibrillation. In one of these patients the drug also produced auricular fibrillation and a tachysystole of the ventricles, which lasted on and off for several hours at one time. In one patient with already established ventricular fibrillation the intracardiac injection of 1 mg. of drug seemed to perpetuate the mechanism resulting in alternating periods of ventricular fibrillation with tachysystole lasting over thirteen minutes and ending in death. The authors consider that as a therapeutic measure epinephrine is a life saving drug in patients in whom syncopal seizures are due to a slowing of the ventricular rate. It is distinctly contraindicated in those in whom the attacks are the result of ventricular fibrillation, and its indiscriminate administration in such patients may result in death.

Polyneuritis Gravidarum.—Wilson and Garvey present the case histories of three patients who showed signs of extensive polyneuritis associated with pregnancy. There was also a profound mental disturbance in each instance, and at the onset of the illness severe and persistent vomiting. *The authors* feel that they satisfactorily excluded such toxic agents as alcohol and lead and also infection as possible etiologic factors and feel justified, therefore, in ascribing the origin to a toxemic process associated with pregnancy. It is impossible to make any definite statements in regard to the exact etiology, and for the present the condition must remain in the category of unsolved problems in common with the other toxemias of pregnancy.

Coagulability of Blood in Pregnancy.—Tests for determinations of the coagulation time were performed by Bland and Goldstein on 100 nonpregnant women and on 400 gravid patients in the various periods of pregnancy. Additional tests were performed on 100 patients during the lying-in period. It was found that only 36 per cent of 100 normal nongravid individuals gave a clotting time ranging between one and five-tenths and two and five-tenths minutes, whereas the coagulation was completed in 349, or 87.2 per cent, of the 400 women examined in pregnancy before two and five-tenths minutes. On the basis of these results one may safely conclude that the coagulability of the blood (as shown by the test employed) is relatively increased in pregnancy. Because of the small differences in the clotting time of the pregnant and nonpregnant individuals, it is the feeling of the authors that this test cannot be relied on to disclose the efficiency of the mechanism of coagulation. The results of the test in the puerperal period show that there is a rather sharp tendency for the readings to return to the values found in the nongravid state.

Intraperitoneal Hemorrhage of Ovarian Origin. — In twenty-one out of twenty-six cases of intraperitoneal hemorrhage of ovarian origin studied by Sackett, the symptoms were related to the bleeding ovary. In five cases (19.2 per cent) the other pathologic changes in the pelvis entirely overshadowed the bleeding. Microcystic degeneration as a cause of ovarian hemorrhage was not sustained, although both conditions may be manifestations of a disturbance in the growth, maturation, rupture and metamorphosis of the follicle. The wide variety of normal and pathologic alterations of the ovary is shown by this series. In the light of these factors, trauma seems only to hasten or aggravate a condition already destined to occur. Correlation between menstrual history, onset of symptoms, and the cyclic stage of the removed ovarian and endometrial tissue should in the future add to the knowledge of the pathogenesis and diagnosis of the condition. Massive ovarian hemorrhage will be mistaken by careful observers for ruptured extra-uterine pregnancy unless due weight and credence are given to the clinical history and social status of the patient. The attendant should refrain, whenever the social status of the patient precludes legitimate pregnancy, from making the diagnosis of ectopic pregnancy until it is proved by pathologic examination. Discrete ovarian hemorrhage will be mistaken for acute and subsiding acute appendicitis and lead to unnecessary operation. If the onset of pain is correlated to the estimated ovulation time as well as to the date of menstruation, and if this relation applies to the previous attacks, one may suspect the ovary; and a rapid fall in the leukocyte count and sedimentation rate points to cessation of bleeding as well as absorption of the effused blood. The occurrence of ovarian hemorrhage due to trauma per vaginam adds another to the classic indications for the correction of retroversion and ovarian prolapse.

Hypothyroidism.—Breckinridge emphasizes the fact that *slight to moderate degrees of hypothyroidism may be causal* factors in amenorrhea and, more frequently, menorrhagia and probably abortion, miscarriage, premature labor, and death of the fetus. Hypothyroidism is one of the more frequent causes of menorrhagia and metrorrhagia and should be excluded before resort is had to the curet, radium, roentgen rays or abdominal section.

Delayed Chloroform Poisoning.—Stander gives the mortality in delayed chloroform poisoning as about 80 per cent. Intravenous dextrose therapy and antiacidosis measures, such as sodium bicarbonate intravenously, offer the only hope of recovery. The author believes that chloroform should not be used in any surgical procedure, except by an expert anesthetist especially schooled in its use. The only place for chloroform in obstetrics is late in the second stage, when it should be administered in whiffs (anesthesia à la reine); and even then it should be used only when no other anesthetic is available or indicated.

Electrosurgery.—According to Boland, the scope of electrosurgery to the general surgeon is increasing in application. Brain tumors, neoplasms of the skin and mucous membranes not involving vital structures, epitheliomas, polypi, papillomas, hemorrhoids, cervical erosions, urethral caruncles, leukoplakia, lupus vulgaris, moles and warts are among the many conditions in which this modality has been applied. The laryngologist finds use for the application in tonsil work, nasal polypi, carcinoma of the larynx, leukoplakia, pharyngeal bands and remnants of tonsillar tissue. The author believes that the recent advancement in McCarthy's technic in urology will in ten years eliminate 50 per cent of prostatic operations. Trowbridge's success in extensive postoperative abdominal adhesions affords a new approach for the relief of this class of sufferers. Its application in breast and rectal work has been utilized extensively. The employment of some form of electrosurgery together with the proper technic is the better method of treatment in localized cancer or allied lesions of the skin or mucous membranes.

Injection Treatment for Varicose Veins. — Stoner believes that in the injection treatment the danger of embolism is undoubtedly underestimated and is to be reckoned with. This accident should be reduced to a minimum by a familiarity with the conditions underlying the disease processes, and one should be prepared to carry out and interpret all the necessary tests essential to proper selection of cases. There is no one ideal solution in use that is always effective or fool proof.

Should a slough result, the author prefers to treat it conservatively, bringing the walls together with adhesive strips after the separation of the necrotic core. Radical excision of the slough should be done only in a hospital operating room. A complete physical examination of the patient and careful preparation of the limb are essential before any injection is attempted. At the present time, however, the author knows of no infallible means of preventing certain serious reactions and even grave disasters that occasionally follow the treatment. Recanalization of injected veins may occur and varicosities may develop from apparently normal veins after injection and will require treatment. All patients, therefore, should be kept under observation for a year or longer.

Differential Diagnosis of Surgical Conditions of Abdomen from Intercostal Neuralgias.—Feldman states that intercostal or parietal neuralgias often mimic acute surgical conditions of the abdomen. Heretofore experienced clinical judgment was the only means of differentiating the two conditions and then not always correctly. Low subarachnoid block causes a relative separation or dissociation of the spinal cord and the ganglionated sympathetic cord for a varying interval. This surgical or diagnostic interval is particularly noticeable in surgical lesions of the upper half of the abdomen. Parietal anesthesia and visceral anesthesia do not appear simultaneously; parietal anesthesia appears before visceral anesthesia and they both appear from below upward. There is therefore an interval which allows time to determine whether the pain is parietal or visceral. The rate of ascension of spinal anesthesia depends on the height of injection of the anesthetizing agent, force of injection, amount of spinal fluid withdrawn and the amount of fluid injected, the physical and chemical nature of the injected agent and the position of the patient before and after injection. Spinal anesthesia as an aid in the differential diagnosis between acute surgical conditions of the abdomen and intercostal or parietal neuralgias should be so induced as to allow of slow ascension of the anesthesia along the spinal cord.

Histopathology of Nasopharyngeal Neoplasms.—Beck and Guttman call attention to two relatively newly described types of malignant epithelial neoplasms of the nasopharynx; namely, epithelioma and transitional cell carcinoma. These growths are characterized by a specific unique histology, a small and frequently undetectable primary lesion, early cervical metastasis and pronounced radiosensitivity. The biologic properties of these neoplasms contraindicate surgical intervention, while their radiosensitivity renders them especially suited for treatment by irradiation.

Zinc Ionization Treatment of Middle Ear Infections.—Lierle and Sage believe that the possibility of the deposition of metallic zinc in living tissue is remote and open to question. The spectroscope is particularly adapted to the detection and estimation of small amounts of zinc in tissue. The use of small electric currents in the treatment is of doubtful value so far as the bactericidal effects of such currents are concerned. The authors have studied the value of zinc sulphate as a bactericide. They consider that the beneficial effects of zinc ionization treatment in middle ear infections are probably due primarily to the destruction of bacteria by the zinc sulphate; the effect of the current is of slight importance.

Chondroma of Larynx.—According to Figi, the treatment of chondroma of the larynx depends on the situation of the growth, its size, the character of its attachment to the laryngeal cartilages and its activity. The usual benign character of these tumors amply justifies decided conservatism. Laryngectomy is indicated only in case the growth is so extensive that its complete removal would leave a nonfunctioning, collapsed larynx. Adherence to a conservative policy is likely to result in secondary operative procedures becoming necessary in an occasional case, but with the possibility of preserving laryngeal function this risk seems well worth assuming. Removal by indirect laryngoscopy, peroral endoscopy or under suspension is feasible in cases in which the tumor is small and pedunculated or attached to the epiglottis. In the majority of the cases laryngofissure and enucleation of the growth, together with its capsule, is the treatment of choice. This procedure is especially satisfactory in dealing with tumors in the subglottic region, particularly in the posterior portion. In three of six cases of chondroma of the larynx reported by the author, the patients were treated in this manner with entirely satisfactory results. In cases in which a fairly large tumor is situated in the supraglottic portion of the larynx, subhyoid pharyngotomy may offer more satisfactory surgical approach. Preliminary tracheotomy may be advantageous with any method of operative treatment, especially if the tumor is producing respiratory obstruction. The procedure is advisable in cases in which laryngectomy is required, as the operation can then be carried out more safely as a secondary stage. In some of these cases it has been deemed advisable to observe the tumor during the course of weeks or months in order to determine its activity before deciding on the type of treatment. Obviously an actively growing tumor will require more radical measures than one of the same size but of slower growth. In the latter instance it might be possible to enucleate even a large neoplasm, whereas in the former laryngectomy would probably be required.

Adenoids and Upper Respiratory Disease.—Gafafer observed a group of 317 adults for thirty-five weeks from Sept. 29, 1929, to May 31, 1930, when an effort was made to secure reports of all attacks of upper respiratory disease (common cold). Of these adults, 235 showed adenoids and 82 did not. The group with adenoids present and the group with adenoids absent showed no significant difference in respect of (1) frequency, (2) severity or (3) type of attack of upper respiratory disease.

Deafness, Hepatic Dysfunction, Pancreatic Insufficiency.—Gottlieb describes a condition that may be termed "aurohepaticopancreatic syndrome," the cardinal symptoms of which may be listed under three headings: (1) cranial (tinnitus, progressive loss of hearing, vertigo, falling, headache [migraine], and blurring of vision); (2) digestive (constipation, occasionally diarrhea, belching, pyrosis, flatulence, fulness and discomfort after eating), and (3) general (fatigue). The positive objective signs are lowered basal metabolic rate, increase in the number of small lymphocytes in the blood, increased indican in the urine and a definite abnormality in the duodenal fluid, which is manifest by a reduction in the amount of cholesterol, furfural number, and alcohol soluble and alcohol insoluble bile pigments. Traces and total absences of these are frequently recorded. In addition to this, there is a reduction in the digestive activity of the pancreatic ferments, the lipolytic element being most often depressed.

Method for Control of Postnasal Hemorrhage.—According to Beavis, the technic and apparatus used in the Department of Otolaryngology, University of Michigan, for the control of postnasal hemorrhage is as follows: A Morrison frame is attached to the patient's bed in the usual manner. A firm dry gauze postnasal tampon is prepared and around its middle a piece of woven silk such as that used in maxillofacial surgery is snugly tied. A well lubricated medium-sized urethral catheter is passed through the left common meatus of the nose down into the nasopharynx and out through the mouth. The free end of the woven silk carrying the tampon is tied to the end of the catheter protruding from the mouth, and by retraction of the catheter the postnasal tampon is pulled firmly back into the nasopharynx, with the free end of the silk emerging from the left naris Another piece of silk is tied to the strand coming out of the nose and led over a pulley fixed to the frame of the bed. Light weights are attached to the silk line to produce a constant tension on the pack in the nasopharynx. The pull on the tampon can be readily adjusted by changing the weights. By this method constant firm pressure sufficient to control hemorrhage can usually be maintained within the postnasal space, though the patient is free to move the head in all directions. It likewise obviates the necessity of anchoring the silk line carrying the tampon to some part of the head, a procedure that is often painful through injury to the ala or upper lip.

Complications Associated with Major Proctectomy. A. O. Whipple, New York.—p. 916.

Acute Intestinal Obstruction.—Vidgoff believes that the mortality of intestinal obstruction can be reduced only when the patient is operated on early. The patient is often as much at fault as the physician. The clinical picture is not always clear, and operation should not only be advised but insisted on on suspicion that intestinal obstruction is present. To wait for the full clinical picture to develop will greatly reduce the patient's chances for recovery. Adhesions are the commonest cause of obstruction. To eliminate these cases it is necessary to operate for acute appendicitis early and to peritonealize raw areas fully in pelvic operations. While the "flat plate" roentgenogram is a distinct aid in urging the surgeon to operate, it is not essential in the diagnosis. In the cases studied by the author there was apparently little change in the blood chlorides in those patients who died in comparison to those who recovered. Patients did not do better with the administration of hypertonic solution of sodium chloride than of physiologic solution of sodium chloride. The important factor was the fluids supplied. Enterostomies do not lower the mortality except in some cases of adynamic ileus. If enterostomies are done, one should drain the intestine on the table by cutting it rather than using a catheter. When there is interference with the blood supply to the intestine, it is best to empty the contents of the intestine while the patient is on the table.

Acute Intestinal Obstruction.—In Cornell's series of 235 cases reported under the diagnosis of acute intestinal obstruction, the mortality was 51.48 per cent. The average age of the patients was 32 years. There were 118 males and 117 females. The average duration of symptoms before treatment was 3.9 days. Plain roentgenograms are helpful in early diagnosis of acute obstruction to the intestine. There were 218 operations, 17 cases in which operation was not performed, and 49 secondary operations, with an operative mortality of 58.4 per cent. Previous abdominal operations are a definite etiologic factor for later obstruction, especially in the band group of cases. The duration of obstruction before surgical correction is an important factor in the prognosis. The more severe surgical procedures, such as resections, gave a higher mortality than the cases in which it was only necessary to release the obstruction by cutting a band. Primary enterostomy gives a higher mortality rate than a combination of all the other surgical procedures. The author's statistics agree closely with statistics compiled thirty years ago and also with those of today.

Acute Intussusception.—According to Robbins, the surgical treatment of intussusception can be divided into three groups: (1) easily reducible, in which no further surgical treatment is indicated; (2) the irreducible, without gangrene, in which the author recommends the operation suggested by Brown or the modification suggested by Johnson, and (3) the irreducible and gangrenous, in which he recommends resection and immediate anastomosis. Successful resection for intussusception is not so rare as is generally believed and probably should be done more frequently before the intestine is subjected to too much trauma. The author reports a case which, from his search of the literature, seems to be the most extensive successful resection for gangrene in intussusception yet reported in a child aged 7 weeks.

Massive Intestinal Resections.—Owings and Smith describe experiments in which they demonstrated that massive resections of the intestine are feasible on very sick animals, giving a low mortality rate if done quickly and with careful technic. The point at which resection is safe can be determined with a fair degree of accuracy if certain principles are adhered to. The best things to judge by are, first, the ability of the intestine to contract when mechanically stimulated; that is, not only ability to contract but to contract completely, go into actual spasm. This spasm is readily induced by tapping the intestine with a clamp or pinching it or plucking it with the finger. It is important to notice whether the intestine at the height of its contraction comes down to the size that one would expect normal intestine to reach under similar stimulation, because this helps to determine the degree of edema, which is the best expression of the early reaction of the intestine to obstruction. The circulation of the intestinal wall and the mesentery is highly important. There should not be any edema of the mesentery, and pulsations should be clearly seen and felt in the mesenteric vessels. The circulation in the intestinal wall itself is best determined by its color during both spasm and relaxation. During relaxation, a point should be picked where the color of the intestinal wall changes from the dusky, nonglistening color of damaged circulation to a point as near the normal pinkish glistening color as possible. This point is hard to determine, as the change is a gradual one and the normal color is never actually reached. One has to be governed by the comparison and by experience, together with the other points brought out. The wall at the point of resection when in the spastic stage should be nearly white, showing that the capillaries are not thrombosed, since the blood is expressed from them by the force of the contraction. In obstructed intestine when the circulation is damaged and there is beginning gangrene, even though the intestine will contract it remains rather dusky, probably because of thrombosed capillaries.

Congenital Duodenal Adhesions.—Knox calls attention to the fact that congenital duodenal adhesions are an important clinical entity having a definite train of symptoms and should be borne in mind particularly by those called on to operate on infants. Though the cause of congenital duodenal adhesions has received investigation, no one seems to have advanced a theory that adequately explains their formation. The adhesions may be the result of infection which originates from intrauterine sources, traveling through or along the umbilical vessels, falciform ligament or portal vein to the under surface of the liver or subhepatic fossa. The adhesions in six cases reported by the author all extended from the anterior surface of the duodenum to the under surface of the liver in close proximity to the gallbladder. The duodenum was pulled upward and to the right, producing definite kinking. The portion proximal to the adhesions was distinctly dilated, and, as the adhesions were severed, the gas was seen to pass into the distal portion. The stomach was dilated in each instance and this dilatation also was relieved after the adhesions were separated. The symptoms of congenital duodenal adhesions are so similar to those of hypertrophic stenosis that one is led to this as a diagnosis; and when at operation no stenosis is found, one should explore the subhepatic fossa for the presence of adhesions. The chief subjective signs are vomiting, constipation and loss of weight in a fretful, hungry and dehydrated infant, while objectively there are visible gastric peristalses. The vomiting occurs immediately after birth. In the early stages liquids are rejected almost as soon as they are swallowed, while as time goes on, the stomach becoming dilated, vomiting does not occur for some time after feeding and then may become cumulative as well as projectile. Bile is usually absent in the vomitus in the early stages, but a small amount may pass the obstruction and then the vomitus will be bile-stained. The lack of absorption accounts for the constant hunger, the persistent constipation and the progressive emaciation and dehydration. As the stomach dilates and the loss of weight continues, gastric peristaltic waves become visible. Commencing in the left hypochondriac region, they pass across the epigastrium, culminating at the pyloric region. Occasionally, the waves may pass beyond, becoming lost under the liver. Since the stomach dilates slowly, early regurgitation rather than projectile vomiting is the rule. Roentgen examination is not essential for a diagnosis, and may, in fact, be misleading. The treatment of congenital adhesions of the duodenum is surgical and should be instituted before dehydration sets in and loss of weight occurs.

Basal Cell Epitheliomas.—Nomland describes a case in which epitheliomas arose in adult life from pigmented basal cell nevi present since birth. No cases identical with the one reported were found in a fairly thorough search of the literature. The closest similarity found was in two cases reported by Adamson and in others of multiple basal cell epitheliomas of the face not arising in keratoses. The lesions described varied from small translucent papules to large rodent ulcers, but they did not arise in preexisting nevi as in the author's case.

Tuberculosis Cutis.—Levin and Tolmach report an unusual case of tuberculosis cutis occurring in a person with tuberculosis of the lungs and of the left mastoid bone. The cutaneous lesions were very superficial and relatively benign in their course. The diagnosis was made partly on the basis of the clinical appearance of the lesions and positively by the histologic examination and the recovery of the tubercle bacilli after inoculation of a guinea-pig. Difficulty was encountered in differentiating this condition from other cutaneous diseases, particularly from Boeck's sarcoid. The authors believe that the pathogenesis of these lesions is dependent on an attenuated form of the tubercle bacillus.

Xanthoma Tuberosum.—Weingrow presents a case of xanthoma tuberosum with extensive involvement of the tendons, in which the planum variety of lesion was also seen. The sugar, cholesterol and nonprotein nitrogen contents of the blood of this patient were higher than those found in the normal person. The presence of the same type of lesion in the tendons of a brother and of other relatives, a negative Wassermann reaction of the blood and the absence of evidence of other infectious diseases suggest an hereditary tendency. The characteristics of xanthoma as exhibited by xanthoma cells, fibroblastic reactions, deposits of lipoid material, degenerated muscle cells and the resemblance to a malignant condition are presented in the histopathologic studies. Chemical analysis of the blood in two of three additional cases observed by the author revealed cholesteremia, glycemia and a rise in the nonprotein nitrogen. The last has not heretofore been reported in connection with this disease. In two of the cases there was no rise in the sugar content of the blood above normal, and the urine was free from sugar. In three of the cases, including two of those previously mentioned, there was definite evidence of arteriosclerosis. The relation between arteriosclerosis and xanthoma tuberosum has not been observed heretofore. In the third case, there were hypertension and nephritis, primarily, and diabetes secondarily related to the xanthoma tuberosum.

Mycotic Infections of Feet and Hands.—Strickler and his associates say that mycotic infection of the feet, in the light of the new conceptions, can no longer be regarded as only a local skin condition. The lesions of epidermophytosis of the feet are to be regarded as local foci, from which, under certain conditions, absorption of toxic substances (fungous, metabolic or both) can take place. These substances are dermatotropic, acting as skin-sensitizing agents and assuming a rôle in the causation of various secondary (mycid) eruptions. Comparable to this trichophyton fungus phenomenon, mention can be made, for instance, of bacteria that, locked up in various organs, act as local foci of infection and are at times an important etiologic factor in such dermatologic diseases as chronic urticaria, erythema nodosum and erythema multiforme. To a degree, considerable similarity exists in origin and behavior between the secondary cutaneous conditions due to ringworm fungus (epidemophytids and trichophytids) and certain of the tuberculids and secondary syphilitic eruptions. In trichophyton fungus infections in man and in experimental trichophyton fungus infections in animals, ringworm fungi have been found in the blood stream. It appears more than probable that the fungi in the human infections are destroyed rather quickly and early, possibly in the lymphatic channels or in the lymph nodes, and that their main function probably consists in augmenting in some manner the cutaneous sensitizing influence of the hyphomycetic products. That the lymphatic channels can shield and transport ringworm fungi is paralleled by a similar relationship known to exist between the lymphatic vessels and spirochetes. The authors draw the following deductions from a survey of the literature and additional experiments that they cite: 1. In the treatment for the chronic recurrent epidermophytosis of the feet and epidermophytid eruptions of the hands, desensitization of the skin through trochophytin therapy would seem a logical procedure. 2. There is urgent necessity of some form of cutaneous test of just sufficient sensitivity to serve as a reliable and specific diagnostic aid in the etiologic determination of the various squamous and vesicular eruptions of the hands and lichenoid eruptions of the extremities. 3. Complement fixation or related serologic studies are advisable as a means of shedding more light on the nature of the sensitizing influence of the mycotic infections of the feet, and possibly also as a diagnostic procedure.

Self-Sterilizing Powers of Skin.—Cornbleet describes experiments in which he noted that skin folds are less able to inactivate micro-organisms than are other normal cutaneous areas. Their self-sterilizing capacity is still further depressed whenever they become the seat of a pathologic disturbance. When skin folds are opened to the air, their capacity to inactivate staphylococci tends to approximate that of other normal skin areas. This tendency is a function of time; the longer the fold remains open, the closer is the approximation. The total number of organisms inactivated in a closed skin fold bears little relation to time.

Mucous Retention Cysts of Lip.—Monash reports that in the treatment of mucous retention cysts of the lip he has been using a method different from those described, and which can be performed in a physician's office in a few minutes. With the cutting current of an endothermy apparatus, preferably, or with a scalpel, an incision is made through the oral mucosa and into the cyst cavity at one end The cutting instrument is passed round the entire margin of the cyst cavity, thus removing a more or less circular mass of tissue, consisting of the roof of the cyst, made up of the oral mucosa and a portion of cyst membrane No attempt is made to cauterize the floor of the cyst In fact, cauterization is contraindicated in this procedure, as it would substitute a raw surface for one already covered with epithelium No suturing is necessary, and healing is rapid Recurrence does not take place, because any mucus secreted by the floor of the cyst is not retained in a closed cavity but passes directly into the mouth. In time the character of the cyst floor changes to that of normal oral mucosa The author has used the same procedure in the treatment of a hydrocystoma, 0.5 cm in diameter, situated near the outer canthus of the left eye By merely removing the roof of the cyst, including the overlying skin, a complete disappearance of the lesion was obtained, within a few weeks no difference could be observed between the character of the cyst floor and that of the surrounding skin

Injection Treatment of Hemorrhoids C C Neese, Wilmington—p 122
Relations of Delaware Public Health to Indigent Syphilitic Cases A C Jost, Dover—p 124

Diagnosis and Treatment of Carcinoma of Large Intestine.—According to Babcock, carcinomas of the large intestine should be diagnosed early by alterations of the peristaltic function, digestive disturbance, progressive anemia, and by roentgen, digital and proctoscopic examinations Offensive, bloody, mucous stools, intestinal obstruction or cachexia usually indicates a growth of long standing Operative excision, if the growth is not too far advanced, gives a reasonable hope for recovery. Irradiation is ineffective against most of the intestinal carcinomas. From the ileum to the descending colon, an intraperitoneal excision and anastomosis, with careful attention to the preservation of the blood supply of the retained intestine, is the preferred type of operation From the descending colon to the lower rectum a combined abdominoperineal operation is indicated, followed by radical removal of the intestine with the tributary lymphatics, as well as the preservation of an adequate circulation for the retained intestine. The author describes a method of abdominoperineal resection by means of which colostomy is eliminated and the intestine is not divided or invaded until after the peritoneal cavity is sealed. With the higher rectal growths, the sphincter may be preserved; but with the lower ones, a wide resection of the pelvic floor may be necessary. In ten cases in which this operation was used, less shock and reaction followed than after any other type of operation tried For the small, low-lying rectal carcinomas, with slow infiltrative tendencies, a local excision through the enlarged anus may be adequate The advantages of a properly made perineal anus should be evident. It may be cared for with less derangement of the clothing than a colostomy, and it is easily controlled by a pad and rubber sponge pressure. The perineal opening also more surely gives warning of an impending defecation than does the colostomy, and by digital examination one may obtain early evidence of a recurrence in the pelvis at a time when excision or local destruction is effective. All patients observed by the author have considered their perineal anus preferable to a colostomy.

Indications for and Results of Removal of Spleen D. H. Poer, Atlanta—p 233

Transurethral Prostatic Resection Versus Operative Prostatectomy.—Floyd and Pittman feel that transurethral prostatic resection is definitely indicated in some cases of vesical neck obstructions. This is particularly true in the median bars, when there is a fibrous band across the neck of the bladder. In the glandular bars, that is, the solitary posterior commissural hypertrophies, resection is ideal. The entire median lobe can be resected out, leaving an avenue sufficient to empty the bladder. In carcinoma in which the condition is too far advanced when the diagnosis is made to bring about a cure, resection is of temporary value in relieving the obstructions, so that the bladder can be emptied, obviating the necessity for a suprapubic tube. The authors have been advocates of the suprapubic tube in these cases for some time and, owing to its many drawbacks, they are now glad that in these cases the patients can be temporarily relieved without it. In the moderately enlarged and early prostatic hypertrophy this procedure is of definite value, because the back pressure changes in the kidneys and bladder are not far advanced. The authors do not feel that resection can take the place of operative prostatectomy for the markedly enlarged prostates. In this type of case they intend to continue with the usual method of prostatectomy. Finally, they emphasize that this is not a simple procedure, for it requires not only a thorough knowledge of the anatomy and pathology of the posterior urethra but also skill and experience in manipulation of the resectoscope.

*Pathology of Nineteen Cases of Peculiar and Specific Form of Nephritis Associated with Acquired Syphilis A R Rich, Baltimore—p 357
*Hyperthyroidism and Diabetes Mellitus E C. Andrus, Baltimore—p 383

Nephritis Associated with Syphilis.—Rich describes a peculiar and heretofore unrecognized but not uncommon form of nephritis associated with acquired syphilis. It was found in 6.5 per cent of 200 necropsies in which there were definite syphilitic lesions in other organs, and in five additional cases in which no other syphilitic lesions were found at necropsy but in which there was definite clinical proof of the existence of syphilis (positive Wassermann reaction). Although diligently searched for in 400 control necropsies, in no instance was the lesion found in the absence of syphilis. The author presents evidence that the lesion represents a true *syphilitic* nephritis and discusses the relation of the process to clinical nephritis occurring during the course of syphilitic infection.

Hyperthyroidism and Diabetes Mellitus.—Andrus presents the clinical courses of two patients in whom diabetes mellitus and hyperthyroidism coexisted. The carbohydrate metabolism in hyperthyroidism is contrasted with that in diabetes mellitus. In the presence of hyperthyroidism this is at fault less as regards the ability of the organism to store carbohydrate than in the abnormally rapid breakdown of glycogen. The diabetic patient, on the other hand, suffers from a limited carbohydrate tolerance; carbohydrate administered in excess of this appears in the urine as dextrose. Hyperthyroidism superimposed on diabetes mellitus creates abnormal demands on an already inefficient carbohydrate metabolism by augmenting the basal metabolic rate and by enhancing glycogenolysis.

Anaphylaxis to Diphtheria Toxin.—Sugg and his associates report that the offspring of antitoxin immune guinea-pigs gave anaphylaxis when injected intravenously with toxin-containing material thirty to sixty days after their birth. Sufficient controls were made on the possibility of participation of nontoxin antigens and of nonantitoxin antibodies to justify the conclusion that the anaphylaxis was due to reaction between the toxin antigen and the placentally transmitted antitoxin. The advantage of the use of carefully selected offspring was demonstrated by the high degree of completeness of nonreactivity to nontoxin diphtheria antigens that was exhibited by the offspring of individual mothers whose serum contained no diphtheria antibodies other than antitoxin or only small amounts. Apart from the question of toxin anaphylaxis, the authors' demonstration of anaphylaxis to diphtheria material on the part of the offspring of immune guinea-pigs is of interest as an example of placental transmission of hypersensitiveness to an antigen of bacterial origin.

*Erysipeloid: Bacillus of Swine Erysipelas Infection: A Disease of Industry. J. V. Klauder, Philadelphia.—p. 222.

Cod Liver Oil and Milk as Dietary Supplements.—Sixty-three underweight young women served as subjects of an investigation conducted by Holmes and his associates to determine whether cod liver oil and milk taken as supplements to the usual home diet of substandard women would improve their health and efficiency. All the women were employed at tasks classified as light muscular activity. Cod liver oil of known history and high grade commercial milk were ingested in the forenoon and afternoon rest periods. A daily record was made of attendance and the cause of previous absences and illness. Weekly records were made of body weight and efficiency rating. It was noted that the use of cod liver oil and milk as supplements to the usual home diets of the substandard young women was followed by an increase in body weight, a decrease in absences from employment, an increase in efficiency rating, and an improvement in the menstrual irregularities experienced by some of the women. It is therefore apparent that the addition of cod liver oil and milk to the usual home diet contributes materially to the well being and efficiency of underweight young women dependent on their ability to work for a livelihood.

Erysipeloid.—Klauder calls attention to the fact that the bacillus of swine erysipelas is widely disseminated; its habitat is dead matter of animal and plant origin. The organism is either pathogenic or saprophytic throughout the animal kingdom. In swine, which are more frequently infected than are other animals, it causes an infection known as swine erysipelas. In man, the mild form of the infection is most common, occurring at the site of injury, invariably on the hand, and appearing as a purplish red erythema of a migratory character. Pain and swelling frequently cause incapacitation. The disease may spontaneously involute in from two to four weeks. In exceptional cases it extends above the wrists and persists for weeks and sometimes months. The acute fatal form and the arthritic form of the disease in man are rare. The infection is common among commercial fishermen working in fishpounds, handling live fish. It intimately concerns handling spiny fish as well as slimy fish. Spiny fish increase the incidence of trauma of the hands, which serve as a means of inoculation. In all probability the organism is a saprophyte on the slime of fish. The infection is an important disease of the fishing industry. The disease also occurs among employees in the meat packing and canning industries, among food handlers, and among workers in industries in which living or dead animal matter is handled. Local treatment is of no great value. Immobilization of the part and application of heat are the methods generally advocated. The most satisfactory treatment, in the author's experience, however, is the local injection of immune serum.

Aneurysm of Renal Artery.—Mathé reports a case of true aneurysm of the renal artery associated with nephrolithiasis. The aneurysm was secondary to trauma and was successfully relieved by nephrectomy. Aneurysm of the renal artery is an extremely rare condition, only fifty-six cases having been reported to date. In 40 per cent of fifty-five cases reviewed there was a history of weakening and injury of the vessel wall by previous trauma, and in the remainder a history of severe infectious disease of some type, producing lowered resistance due to sclerosis, fatty degeneration, or inflammatory changes of the renal artery. Aneurysm of the renal artery is exceedingly difficult to diagnose, only seven of the reported cases having been detected prior to the time of operation or death. The cardinal symptoms are hematuria, pain and tumefaction. This hematuria is usually more sudden and more extensive than that caused by other kidney lesions. Pulsation and systolic bruit, although rare, are pathognomonic signs. The presence of a ring-shaped opaque area in the kidney should make one suspect renal aneurysm. The treatment of renal aneurysm is surgical. In all the untreated cases, thirty-six of which have been reported in the literature, the patients died Sixteen of the seventeen on whom nephrectomy was performed survived Resection of the aneurysm is occasionally possible Plastic repair of the aneurysmal sac, drainage of the accompanying hematoma, and other surgical procedures less radical than nephrectomy or excision give little, if any, relief

Value of Intravenous Pyelography—Dournashkin states that in the presence of apparently complete calculous obstruction of the ureter, intravenous pyelography frequently supplies the only medium for ascertaining renal function on the affected side In the greatest majority of chronic ureteral stone cases observed by the author, intravenous pyelography demonstrated perfect renal drainage In many cases little difference was noted in the outlines of ureteropelvic tracts on both sides The presence of impassable obstruction is not a criterion that determines complete impaction as in many such cases perfect drainage was revealed by intravenous pyelography The temporary nature of absent ureteropelvic shadows, following the injection of the dye in cases of acute block and those of chronic renal hibernation,' should be constantly borne in mind lest it should be confused for instances of permanent renal destruction in which cases the dye may be similarly not excreted Intravenous pyelography is of no value in localizing uric acid calculi In no case should a patient be submitted to an open operation unless its indications are clearly defined by intravenous pyelography

Pressure of Urine in Renal Pelvis—In the course of certain experiments undertaken for the purpose of studying the pressure of urine in the renal pelves (the so-called secretion pressure) of intact dogs on which bilateral abdominal ureteral transplantation had been performed McCaughan noted that the pressure immediately following simple water diuresis was increased approximately 20 per cent over the maximal pressure obtained under ordinary conditions and only after many minutes of continuous recording The author describes experiments in which he demonstrated that the secretion pressure of the urine following renal denervation is not significantly increased

What Change in the Medical Practice Act Is Most Needed? S Rushmore Boston—p 1211

Raynaud's Disease.—White reports six cases of typical Raynaud's disease, with observations on the immediate and late effects of sympathetic neurectomy Resection of the two upper dorsal ganglions or of the second to fourth lumbar ganglions brought about an immediate paralysis of sympathetic tonus in each case Whereas vasomotor paralysis following lumbar sympathectomy has been permanent, the dorsal operation has been followed by a recurrence of sympathetic nerve function in two out of the six cases reported and in five other cases Sympathetic nerve activity reappeared at the end of six months, accompanied by the color changes, pain, coldness, and ulceration in the tips of the fingers characteristic of Raynaud s disease When the regenerated vasoconstrictor fibers were again adequately blocked by procaine hydrochloride or by reoperation, there was a second disappearance of the manifestations of the disease Therefore, resection of the first and second dorsal sympathetic ganglions alone is insufficient to cause a permanent vasomotor paralysis of the arm In the author's recent cases, in which the operation has been extended upward to include the inferior cervical ganglion, he is hopeful that the results will be as permanent as those in the lower extremity Advanced stages of the disease with long standing ulceration and sclerodermatous changes may fail to recover completely after vasomotor paralysis These instances are satisfactorily explained by Lewis's theory of local pathologic changes in the digital vessels From the theoretical standpoint, early uncomplicated cases of the disease may be explained either on the basis of Raynaud s original conception of a vasomotor neurosis or by Lewis s theory that normal vasoconstrictor impulses cause the attacks of partial asphyxia by acting on abnormal digital arterioles Certain objections have been pointed out against each hypothesis It is therefore essential to reserve final judgment until the evidence in favor of one or of the other becomes unequivocal

Rabies.—Fetherston and Cooper report four deaths from among eight persons bitten on the hands by the same rabid animal: In all these cases it was not the fear of liquids that was manifested but absolute fear of water. Two characteristic early signs in these cases were vertigo dilatation of the pupils, and numbness either of the side on which the bite occurred or of the whole body. This numbness later changed to a hyperesthesia of the skin all over the body. The authors believe that it is a good treatment to dissect out the scars where the bite occurred, if the patient is seen long after the bite. The four patients who failed to contract the disease were taken to the operating room and all scars and surrounding tissue dissected out as soon as the fourth case began to develop. It is believed that the virus develops at the site of the original portal of entry into the body and that it is gradually disseminated into the system from that point. This treatment is given in addition to cauterization with nitric acid at the time of the bite and administration of antirabic treatment. The need of a short course of treatment is evidenced by the remaining four persons who were bitten. After the death of the fourth patient, three of those remaining began to show leukocyte counts from 12,000 to 15,000, which persisted for a few days, but they had already received nearly half of the course of twenty-five injections, and the authors believe that they established their immunity to the infection just in time to prevent them from contracting the disease.

Digitalis.—Zur-Linden believes that the United States Pharmacopeia does not go far enough when it makes mandatory the biologic assay of digitalis. It should also insist that the manufacturer shall state on his containers the date of manufacture and biologic assay, so that tincture of digitalis used at the bedside will be dependable and will produce definite heart stimulation. The author's past experience would lead him to recommend only the use of the whole leaf tablets that have been stored in amber glass tubes bearing the date of manufacture and biologic assay as determined by the United States Pharmacopeia frog method or Hatcher's cat method.

Congenital Speech Defects.—Allen discusses the conditions that result in delay in learning to speak and speech defects apparently congenital in origin and describes illustrative cases. He states that delay in learning to speak and speech defects may be produced by disturbances of hearing or of the ability to appreciate the meaning of word-sounds, by conditions leading to defective mental development, or by conditions which prevent the development of normal control over the muscles of articulation. Psychologic situations can produce defects which may be confused, on a superficial examination, with those due to gross organic defects. Further evidence is adduced to show that the fundamental cause of congenital auditory imperception and of its resulting speech defect is probably a bilateral cortical agenesia affecting parts of the cerebral cortex concerned with the interpretation of sounds. The potentially normal mentality of children suffering from this defect is again emphasized. The exact nature of the speech defect can rarely be determined from the study of the speech itself. The final diagnosis is usually made from the study of the individual by both physical and psychologic methods. True idioglossia is associated only with inability to appreciate the meaning of word-sounds, though the speech of imbeciles and of children of poor psychologic development may give the impression that such children are using an individual language.

Carcinomatous Gastrocolic Fistula Simulating Enteric Fever: Case. T. G. Starkey-Smith.—p. 982.

Carcinoma of Colon.—Gordon-Watson calls attention to the fact that in carcinoma of the colon more than half the growths involve the pelvic colon, and in a considerable number of these the diagnosis can be made with the sigmoidoscope. While a probable diagnosis can frequently be made on clinical symptoms and sometimes confirmed by palpation, an absolute diagnosis is more often obtained by roentgen rays. Roentgen rays may be misleading, and certain fallacies must be borne in mind: (1) Feces or gas in the bowel, or air in the enema may give an apparent filling defect; (2) delay at the rectosigmoidal junction or at the junction of the pelvic and descending colons may be nonpathologic, and (3) spasticity may occasionally simulate the filling defect due to a tumor, especially in the distal half: in such instances a further examination is made after the injection of atropine to relieve spasm. The barium meal and the barium enema both have their values. A meal requires repeated observation to visualize a filling defect, whereas an enema visualizes the contour of the colon throughout, or up to the point of obstruction, at one inspection in a much shorter time. The enema, by expanding the colon beyond the normal, emphasizes any irregularity in contour. An ordinary roentgenogram of the abdomen, without the use of barium, may be quite useful in showing distention of some portion of the colon with gas. This is sometimes of great value in assisting diagnosis in cases of acute obstruction, if the patient is not too ill to be examined. In such circumstances an obstruction (for example, in the pelvic colon) may come out quite clearly. It is probable that there are few situations in the body where radical operation for carcinoma offers such promising results, especially in early cases. A wide resection and anastomosis is as a rule not difficult. The lymphatics run with the vessels and converge on the apex of the resected mesentery. Lymphatic spread is usually slow, and if colloid cases are excepted the grade of malignancy of adenocarcinoma of the colon is low. This is especially true of the hypertrophic type. While it is true that in cases favorable for radical surgery the prognosis is good, meticulous care is required for radical surgery to be successful. The blood supply of the colon is not so good as that of the stomach; the contents of the colon are dangerously infective to the peritoneum, and gas distention after resection may be disastrous if there is no safety valve. Risks are far greater than in cases of gastric resection, and statistics from all sources show that the operative mortality rate for resections is high, whereas the ratio of recurrence is low in comparison with gastric resections.

Polycythemia and Liver Therapy in Asthma.—According to Moll, polycythemia frequently occurs in true spasmodic asthma, especially in the allergic type. It is often found after a severe attack, or a series of attacks, and may last for varying periods. Usually after a free interval of a month the count tends to fall to a normal level again. Seasonal variations in the red cell count have also been observed, the count being highest in the summer in the pollen-sensitive cases and in the winter in the infective type of asthma. A fall in the red cell count has been found to correspond with the lessening in the frequency and severity of the attacks and may therefore be considered as an indication of therapeutic improvement. Liver therapy was tested by the author in fifty-three cases of asthma and proved beneficial in 60.3 per cent of the cases. It was found to be most effective in the allergic type of asthma and in those cases showing an initial high red cell count. In the course of liver therapy a fall in the red cell count was observed in those cases which had shown improvement on the treatment.

Mean Temperature in Nonfebrile Patients.—Lyon and Wallace noted that the mean body temperature in a series of 250 nonfebrile hospital patients who were confined to bed was 97.2 F. at 7 a. m. and 97.45 F. at 7 p. m. They suggest that the heavy line marked on clinical thermometers and temperature charts corresponding with the figure 98.4 F. is misleading, since this figure represents the mean temperature in active life and not the upper limit of normality in a patient lying in bed.

Preliminary Note on Occurrence of Incomplete Development of Striated Muscle Fiber as Cause of Certain Congenital Deformities of Extremities. D. S. Middleton.—p. 389.

Studies in Blood and Tissue Reactions.—Harvey and Hamilton describe experiments in which they demonstrated that there is an invariable sequence of events in response to the introduction of foreign material into the body, a polymorphonuclear leukocytic infiltration followed by a monocytic and, *if time* allows, a *lymphocytic*. The *lymphocyte*, *monocyte*, macrophage and giant cell probably represent stages of development of one and the same type of cell. No matter what the nature of the stimuli (trauma injection of solution of sodium chloride, india ink, staphylococci, tubercle bacilli or benzene; ingestion of food or fluid; posture; application of heat; muscular exercise) they all produce the same sequence of events so far as cell response in the tissues or in the blood is concerned. There is not yet sufficiently conclusive evidence, except by extension of the local influence and of deficiency of cells, for chemical action at a distance as a factor in the production of blood and tissue cell response. One may speak of a positive chemotaxis in the sense of collection of cells to a focus but not in the sense of a specific call for a special type of cell. It is doubtful whether negative chemotaxis exists at all. The special tissue manifestations and blood pictures attached to particular diseases and assisting in their diagnosis are reducible to manifestations of simple acuteness or chronicity, local tissue destruction, and duration of stimulus, thus making the blood picture a matter merely of the time at which the examination is made. There is nothing specific about the cellular reaction in disease or in physiologic states. There is only variation in the degree and duration of a phase.

Common Heart Troubles. L. Abrahamson.—p. 234.

Clinical Study of Achlorhydria.—Moore states that achlorhydria, besides being found in a certain proportion of apparently healthy persons, in many cases of gastro-intestinal disease and in odd cases presenting miscellaneous disorders, is a *frequent observation in diabetes mellitus* and a still more frequent occurrence in hyperthyroidism and in the nonmegalocytic, "hypochromic" form of anemia; in the latter disease it seems to have causal relationship, either direct or indirect, but in the light of recent work on pernicious anemia even this surmised causal relationship may not be the complete explanation. At any rate, this nonmegalocytic form of anemia is of frequent occurrence, and its adequate treatment with iron in the ferrous form by mouth gives satisfactory results.

Tuberculosis of Middle Ear in Adult.—Wilson calls attention to the fact that tuberculous otitis media in adults is usually secondary to tuberculosis elsewhere in the body. The diagnosis rests on the painless onset of a thin mucopurulent discharge, together with marked deafness rather than on laboratory methods. The only nontuberculous cases in which this is likely to occur are those in which there is an old-standing perforation of the tympanic membrane. Multiple perforations of the *membrana tympani occur in about one third of the cases.* The chances of recovery from the local condition are fair. Secondary infection by pyogenic organisms completely changes the clinical picture and renders the outlook more serious. When this takes place there is a marked tendency to luxuriant proliferation of granulation tissue. The presence of a tuberculous otitis media indicates a severe infection and justifies a grave prognosis of the general condition. Treatment should be confined to simple cleansing of the meatus and the use of mild antiseptics. It is suggested that zinc ionization might give good results in a series of cases. Treatment of the lung infection is of major importance.

Anatomic Basis of Chronic Frontal Sinusitis.—Van der H. Leonhard calls attention to the fact that the frontal sinuses of which the roentgenogram shows a true transverse diameter of less than 3 cm. are rarely subject to a chronic inflammation. The lateral stasigenic (stasis producing) factors are apparently most prevalent in the left sinus, the medial factors undoubtedly predominating in the right sinus. The greater tendency of the right frontal sinus to chronic disease estimated directly is confirmed by the author's data. These data rest not only on the comparison of all the stasigenic factors of all the sinuses of one side together with those of the other but also on the fact that the total number of deep pockets predominates on the right. The author believes that if rhinologists who have seen a great deal of chronic frontal sinusitis would decide to publish the exact number of their well authenticated cases (right and left side separately) in the form of a simple personal statistic, and if those who have at their disposal a great number of anatomic preparations of this sinus would examine for the presence of stasigenic factors (the two sides separately), this interesting question could definitely be settled. It is particularly interesting because the comparison in definite cases of roentgenographic data with the intrasinusal statistics is often able to show one the correct and the shortest way to the appropriate treatment.

*Observations on Abnormalities of Pupils and Iris in Tabes Dorsalis, General Paralysis and Taboparesis, with Consideration of Their Bearing on Pathogenesis of Argyll Robertson Pupil. W. M. McGrath. —p. 362.

Acute Dementia Praecox.—According to Bamford and Bean, there are no characteristic histopathologic changes in the brain in dementia praecox. The most constant feature of the disease is a condition of fibrosis affecting the solid viscera, demonstrable both macroscopically and microscopically. The kidney first and spleen secondly bear the brunt of the fibrosis, and these two organs invariably show the effects of this process microscopically. The other organs are affected to a lesser extent, and they tend to exhibit individual variation. In the authors' experience the usual order of involvement is: liver, suprarenal, testis or ovary, thyroid, pancreas, pituitary and pineal gland.

Abnormalities of Pupils and Iris in Neurosyphilis.—McGrath states that the pupillary phenomenon originally described by Argyll Robertson is a complex one and consists invariably of the following components when it is fully developed: loss of the direct and consensual response to light, retention (not invariably of normal degree) of the response to convergence, trophic changes in the texture and color of the iris, and abnormalities in the dimensions (miosis) and in the form of the pupil. No one of these components is more constant than another, and no one of them is separable from the rest. This, the true Argyll Robertson pupil, is invariably associated with neurosyphilis and is never found apart from that condition. The Argyll Robertson phenomenon commonly develops segmentally, becoming uniform only when fully developed. It is to this segmental development of iris changes that segmental loss of light reaction and pupil irregularity are due. This mode of development indicates that the underlying nervous lesion must be in the peripheral neuron. Observations recorded by the author are not compatible with a central lesion in the midbrain. The so-called Argyll Robertson pupil of nonsyphilitic lesions of the nervous system is clinically distinguishable from the true Argyll Robertson pupil. It is accompanied by pupil dilatation and is characterized by the absence of miosis, pupil irregularity or trophic changes in the iris. Theories as to its pathogenesis have no bearing on the problems presented by the true Argyll Robertson pupil.

Three Fatal Cases of Bulbar Type of Poliomyelitis. W. G. S. Brown. —p. 309.
*Pseudosclerosis of Strümpell-Westphal in Five Members of a Family. F. J. Curran.—p. 320.

Familial Bilateral Acoustic Tumors.—Minski reports three cases of familial bilateral acoustic tumors that occurred in three different members of the same generation. The form taken by the disease is interesting, in that one patient suffered from double acoustic tumors only, one from spinal tumors only, and one from double acoustic tumors and generalized neurofibromatosis. In spite of examination of most of the living members of other generations, no signs of neurofibromatosis could be found in them, and a careful search into the histories of others that were deceased brought to light no data suggesting its occurrence. In all three patients a blow preceded the first signs of the disease, the trauma in each case being local; in case 1 it was on the head, in case 2 on the elbow, where two lumps appeared, and in case 3 on the shoulder. It is probable, however, that the trauma merely first drew attention to the disease. Bone changes were present in two cases. One patient had an osteoma of the rib removed some years ago, and pes cavus, and another had a right lumbar scoliosis.

Pseudosclerosis of Strümpell-Westphal.—Curran briefly summarizes the literature regarding Strümpell Westphal's pseudosclerosis and discusses the differential diagnosis between this condition and possible allied neurologic conditions (especially multiple sclerosis, Wilson's disease and juvenile parkinsonism). The Kayser-Fleischer corneal ring is mentioned as a pathognomonic sign of pseudosclerosis or Wilson's disease. Case reports of five children in one family having this corneal ring with unusual neurologic signs and mental symptoms are recorded. The parents of these children were first cousins.

Dysphagia.—Howarth calls attention to the fact that when a patient complains of discomfort or difficulty in swallowing over any considerable period it is of the greatest importance that a careful examination of the tongue, pharynx and larynx be made at once. In some cases it will be found that a chronic inflammatory process is the cause of the trouble; for instance, a well marked chronic pharyngitis, particularly the hypertrophic type with swollen lateral bands that is produced by postnasal discharge, often gives rise to considerable dysphagia. This is not only on account of the inflamed mucosa being sensitive to the stimulus of the food but also on account of some underlying myositis which may interfere to some extent with proper coordination of the muscular action. Various forms of ulceration at the back of the tongue, on the faucial pillars, or in the pharynx may be responsible, and in this connection are mentioned Vincent's angina, syphilis and malignant disease Apart from the inflammatory disorders, the conditions in the larynx that may give rise to difficulty in swallowing are usually of a serious nature Examination with a laryngoscopic mirror may reveal abnormal conditions in the epilaryngeal region or in the sinus pyriformis A swollen and infiltrated epiglottis and arytenoids may be due to tuberculous disease, a deep crater-like ulcer due to a breaking down gumma or to malignant disease Dysphagia in such cases may be severe and may often be accompanied by pain, which radiates to the ears The difficulty in swallowing is often an early symptom, as any process that causes swelling of the structures at the entrance to the larynx will prevent this from being drawn upward into the base of the tongue, and the food or fluid will touch the swollen epiglottis or arytenoid and dysphagia thus occurs owing to undue spasmodic contraction of the pharyngeal musculature Often fluids present more difficulty than semisolids or solids Under conditions of the esophagus that cause dysphagia the author discusses spasm, congenital stricture cicatricial stenosis, diverticula, ulceration, foreign bodies, malignant disease and various extra-esophageal disorders in which the esophagus is compressed

*Endotracheal Inhalation of Ether G Kaye —p 684

Endotracheal Inhalation of Ether.—According to Kaye, endotracheal inhalation anesthesia necessitates the use of a catheter so wide as practically to occlude the glottis but not so large as to do injury This catheter provides an ample airway but prevents any inhalation of air between the catheter and the walls of the larynx This is necessary for two reasons (1) to prevent dilution of the anesthetic with air and (2) to obviate the risk of aspiration of foreign matter from the pharynx into the trachea, since the return current of air which is a feature of the insufflational technic is absent here When much blood may lie free in the pharynx, the latter may be packed closely around the catheter with gauze, all apprehension regarding aspiration into the trachea being thus removed The catheter, once inserted, is practically an extension of the trachea and obviates all possibility of expiratory obstruction due to the presence of blood or mucus in the pharynx or to falling back of the tongue In the original technic, the catheter was connected to a piece of rubber tubing of suitable length and caliber, at the end of which was attached a source of supply of ether vapor, for example, the bowl of a Clover s inhaler or a perforated tin containing ether In this way air was inhaled and exhaled by the patient across the surface of ether in the container Considerable care was necessary lest fluid ether reach the air passages A more elegant technic is supplied by an adaptation of Magill's method for the endotracheal inhalation of gaseous anesthetics Air supplied from a motor blower or other source is passed across the surface of ether in a container suitably equipped with a tap for the control of the ether concentration and with a guard bottle The ether-laden air then enters a small rubber bag serving as a reservoir It next passes, by means of a metal elbow piece, to the proximal end of the catheter Interposed between the bag and the elbow piece is an exhaling valve so contrived that the patient inhales air from the bag and exhales through the valve Rebreathing occurs only in the catheter and not in the bag, unless the exhalation tension of the valve is adjusted for this purpose

Leukolytic Medication.—Aubertin lists the leukolytic agents and discusses the mechanism of leukolytic medication, its therapeutic effect in certain diseases of the hematopoietic organs and the dangers incurred by its use In patients with lymphatic leukemia, roentgen irradiation of the cervical lymph nodes of one side, the axillary lymph nodes and the spleen should be given twice a week with 500 r A rapid decrease in the leukocyte count results, accompanied by a slow decrease in the relative lymphocytic count and diminution of the volume of the spleen and lymph nodes, ending in a greatly improved general condition The spleen and lymph nodes may be normal and the leukocyte count near normal, but a relative lymphocytosis persists and a slight eosinophilia shows that the disease is only arrested, not cured The inevitable relapse a few months later responds to renewed treatment, but more slowly than the first attack When the blood is nearly normal, treatments should be given every two or three months The patient may be kept in apparent health for from two to four years, rarely longer, but finally dies of a relapse resistant to roentgen rays, or from cachexia In myelogenous leukemia, roentgen irradiation of the spleen and the flat bones or the extremities of the long bones produces in the main the same results, but improvement takes place more slowly. After about twenty treatments, the spleen reaches a subnormal state and the leukocyte count is normal or subnormal with a relative polynucleosis and usually less than 1 per cent of myelocytes This satisfactory state continues from about six months to one year, especially if irradiation is repeated at intervals, but relapse is inevitable and, as in lymphoid leukemia, response to treatment is slower There may be three or four relapses, but the efficacy of the irradiation decreases and the periods of remission become shorter until the patient succumbs in cachexia or from an attack of myeloblastic leukemia Roentgen therapy has no practical value in acute leukemia In aleukemic lymphomatosis the spleen and lymph nodes are reduced in size without appreciable modification of the blood While radium, thorium and benzene theoretically have the same action and the advantage of permitting treatment in the patient's home, the author prefers roentgen rays. He calls attention to the following dangers of leukolytic medication: (1) excessive leukolysis, (2) excessive erythrolysis, (3) hemorrhagic aleukemia (the two latter occur chiefly from use of benzene), (4) toxic accidents by too rapid destruction of leukopoietic tissue and (5) production of embryonic cells and transformation into acute leukemia.

Roentgen Therapy of Pyogenic Granuloma. A. Marin.—p. 1022.

Sodium Borate in Exophthalmic Goiter.—Loeper and his associates consider sodium borate of value in the treatment of exophthalmic goiter. It can relieve the subjective symptoms (agitation, nervousness and insomnia) and the objective symptoms (tachycardia, tremor, thyroid hypertrophy and, after a long period, the exophthalmos). The indisputable signs of its therapeutic value are its effect on the protein equilibrium of the blood and on the basal metabolism. The authors have previously shown with what frequency the protein equilibrium of the blood is disturbed by an excess of serum albumin and a decrease in serum globulin and in albumins precipitated by acetic acid. Sodium borate therapy results in a decrease of the serum albumin, a return of the globulin to normal and an increase in the albumins precipitated by acetic acid. The basal metabolism may be decreased from 10 to 30 per cent. In addition to four cases previously reported, the authors report four new ones in which the emotivity, insomnia, tachycardia and tremor were relieved, the thyroid hypertrophy being decreased in two cases and the exophthalmos in one case. The basal metabolism was increased from 10 to 30 per cent and the disturbed protein equilibrium of the blood modified. The action of sodium borate on the nervous system can be confirmed, but it has not yet been proved that it has a selective action on the thyroid or that it modifies its pathologic reactions. The formula used in treatment is 10 Gm. of sodium borate, 10 Gm. of sodium citrate and 200 Gm. of water. The dosage is a tablespoonful two or three times a day.

Electrocardiogram in Pericardial Effusion. G. Picchini.—p. 300.
*Average Arterial Pressure. R. Lusena.—p. 311.

Average Arterial Pressure.—Lusena reviews the literature of arterial pressure and gives his results obtained in measuring the average pressure of 121 patients with and without lesions of the cardiovascular system. The author has observed that: 1. Medium pressure is modified by strain, as under the action of epinephrine or after venesection. 2. Medium pressure does not indicate the anatomic or functional state of the heart and has no prognostic value in decompensation. 3. Medium pressure is not modified in pneumonia. 4. No tensional formula of maximum and medium pressure exists that characterizes a cardiovascular illness. He believes that the behavior of medium pressure does not explain the long tolerability of aortic insufficiency. He is of the opinion that one cannot substitute medium pressure for minimum pressure.

*Severe Hypochromic Cryptogenic Anemia. G. Antonelli.—p. 283.

Severe Hypochromic Cryptogenic Anemia.—Antonelli describes a case of advanced chronic anemia with febrile manifestations, characterized by constant hypochromia of the red corpuscles, by notable hematic regeneration scarce or absent in the circulation but present in the hematopoietic centers, and by clinical indications of hemolysis which does not present relative myeloid hypoplasia of the mature granulocytes. The histologic alterations consist of siderosis of the liver, spleen, bone marrow and kidneys, an isolated hyperplasia, and hypertrophy of the reticulo-endothelial tissue, mainly in the splenic pulp and the bone marrow. Further alterations are diphtheroid lesions of the intestine, a secondary proliferation of the collagenic tissue and partial osteosclerosis, which, together with the myelosclerosis, have a certain pathogenic importance in the determination of severe anemia. The same hyperplasia of the reticulo-endothelial elements may be considered as the histologic cause of the hematopoietic disturbance culminating in the hematologic syndrome. No definite conclusion was reached regarding the diphtheroid lesions of the intestine; they are believed to be secondary, having slight importance in the determination of anemia.

Case of Embolism of Subclavian Artery. R. Satullo.—p. 944.

Colitis Due to Balantidium Coli.—Moretti states that the clinical symptomatology of his patient revealed an eosinophilia of 5 per cent still present after recovery, with bloody stools and a normal temperature. Balantidium coli was found in the feces and on microscopic examination showed the typical appearance with a large kidney-shaped nucleus and inclusions of bacteria, fat, starch granules, detritus cells and erythrocytes. The author reviews the anatomopathology and the symptomatology and treatment of the disease. He gave his patient 0.04 Gm. of emetine hydrochloride a day and obtained good results. In conclusion he states that, even though the disease is quite rare, it would be found more often if a microscopic study of the feces were made in cases of lesions of the large intestine.

Action of Fluorides in Exophthalmic Goiter and Hyperthyroidism.—Goldemberg states that fluorides introduced in the organism (by either the oral or the intravenous route) have an action on the thyroid hormone by means of which this substance is neutralized or precipitated in the body fluids and tissues and its excessive production is arrested. The gradual diminution of the specific substance causes an amelioration of the clinical symptoms until the recovery of the patient is obtained. The oral administration, however, cannot be resorted to in all cases because some patients show gastro-intestinal disturbances. The author obtained good results with sodium fluoride given intravenously. The therapeutic action of the drug in exophthalmic goiter and hyperthyroidism is evident in a slow and gradual but continuous form. The nervous symptoms are the first to disappear after the first four or five injections. Sleep gradually returns. Tachycardia diminishes (except if the heart is already in a condition of hypersystole or asystole; but even in those cases digitalis therapy, which before the administration of sodium fluoride neither diminished the excessive rapidity of the action of the heart nor restored the tonus to the myocardium, recovers its cardiotonic action when its effects are combined with those of fluoride therapy). The basal metabolism slowly returns to normal or near normal. The size of the goiter diminishes gradually until it almost disappears. Exophthalmos greatly diminishes, although it does not disappear entirely and the tremor rapidly and completely disappears. The author begins the treatment with 2 or 3 cc. of a 2.5 per cent solution of sodium fluoride in distilled water. The dose for the injection is gradually increased from 0.5 to 1 cc. in each injection. This dose is maintained until the amelioration of the clinical symptoms begins to show. Then the dose is gradually diminished to 4 cc. per injection, which dose is maintained all through the series (from fifteen to twenty) of injections. At the beginning of the treatment the injections are given either every day or every other day. As soon as the thyrotoxic symptoms improve, the injections are given at intervals of three or four days. After the patient has received the first series of injections he is not given any more for fifteen or twenty days, when another series of injections at the same interval is given. The series are thus given alternated with periods of rest for some months. Clinical cure, as a rule, appears between the fifth and tenth months of treatment. Some patients who support well the fluoride therapy by the oral route can receive the treatment in a combined form, that is, both by injections of the solution mentioned and by the oral administration of progressive doses of from 10 to 50 drops of a 2 per cent solution of either ammonium or sodium fluoride, in milk, four times a day for fifteen or twenty days. The author claims good results in cases in which antithyroid serum, iodide therapy and roentgen irradiation of the thyroid had previously failed. It seems advisable to continue the treatment for a minimal period of from five to six months and in some cases from ten to twelve months; also to give the patient two or three series of injections every year for the two or three years following the first treatment. The treatment may also contribute in the preparation of the patients for operation in cases of hyperthyroidism with a large and sclerous goiter. Fluoride therapy, because of its neutralizing action on the thyroid hormone, seems to be able also to prevent postoperative thyrotoxicosis. This opinion seems to be supported by the experience of the author in seven cases of severe exophthalmic goiter previously reported in the *Presse médicale* (38:1751 [Dec. 20] 1930; abstr. The Journal, April 4, 1931, p. 1183), and in a case of acute thyrotoxicosis in a patient with exophthalmic goiter.

Influence of Blood on Local Pyogenic Infection.—Nakatani considers it of interest to determine whether an effusion of blood counteracts infection or whether it provides a favorable medium for bacteria. He made experiments on about 240 rabbits, by injecting bacterial cultures such as staphylococci, streptococci or colon bacilli together with blood from the animal into the cavity of the knee, the subarachnoidal space or the pleural cavity. The results of these tests are summed up as follows: 1. Whole blood provides an unfavorable medium for the development of bacteria and seems to prevent the development of inflammation. 2. Defibrinated blood promotes inflammation. 3. Serum in its action is about midway between the two types of blood mentioned and has slight connection with either promotion or inhibition of inflammation. 4. The blood, the coagulation of which has been checked by the addition of heparin or citrate, as a rule promotes inflammation, but if the citrate content is high, inflammation is prevented. 5. The arresting influence that whole blood exerts on inflammation is due to the bactericidal power and to coagulation, particularly to the mechanical action of the latter.

Transplantation of Parathyroids in Parathyroprival Tetany.—Hanke states that after-examinations of two patients who, seven years previously, had undergone heteroplastic transplantations of parathyroids for the treatment of parathyroprival tetany showed that one, who had had a tetany of medium severity, was almost completely cured, and in the other one, in whom the tetany had been extremely severe, there still existed tetany that was sometimes latent and sometimes manifest, but still there was a considerable improvement. In both cases there was a favorable influence of transplantation and in the second case it saved the life of the patient. Because of the gradual disintegration of the transplants, the action is only temporary. The author discusses the requirements for a successful transplantation therapy and points out that although other treatments (protective diet, parathyroid extract and viosterol) have been introduced in recent years, the transplantation method is still indicated for certain cases.

Tuberculosis and Bronchiectasis.—Köttgen estimates the injurious effects exerted by the tuberculous process on the bronchial wall and further mentions secretory stasis and coughing, the latter two factors probably causing dilatation. Then, after having explained the concurrence and the genetic connection of the two conditions, he shows that in other cases it is just as important to differentiate the two disorders, which often resemble each other greatly. Auscultatory examination reveals in bronchiectasis usually many bubbling, sonorous or nonsonorous râles. Percussion is less important in the diagnosis of bronchiectasis. The roentgenogram of the patient with bronchiectasis usually shows only slight changes, which do not correspond to the severe clinical aspects. This discrepancy between the clinical and the roentgenologic aspects is characteristic for the uncomplicated cases of bronchiectasis. The typical sputum of bronchiectasis, which on standing divides into three distinct layers and which has an offensive odor, was formerly considered as of especial significance for the diagnosis, but it is now known that this is a late symptom. Moreover, it is not pathognomonic, for it is observed also in simple suppurating bronchitis. Of great significance are hemorrhages that become manifest either by slight admixture of blood to the sputum or by hemoptysis. This symptom speaks especially in children for bronchiectasis. The temperature is only of slight value for the differential diagnosis, because both diseases are characterized by fever; however, in bronchiectasis the fluctuations are usually more pronounced. The tuberculin test is likewise only of slight value. In the conclusion the author points out that with the exception of contrast filling there is no absolutely reliable method for the differentiation of bronchiectasis and tuberculosis, but in the majority of cases the consideration of all the other symptoms makes a correct diagnosis nevertheless possible, and even if contrast filling of the bronchial tree becomes necessary, this is not difficult if done by one with sufficient experience.

Iodine Therapy of Pulmonary Tuberculosis.—Following a review of the literature, Sylla reports his own observations with iodine therapy of pulmonary tuberculosis. He is convinced that if suitable iodine preparations are used, this treatment can be employed in all forms of pulmonary tuberculosis, except in cases with hemorrhages and in those with new infiltrates. The iodine therapy effects an improvement in the general condition and facilitates expectoration and respiration. In cases of minor severity it effects increase in weight, reduction of temperature, decrease in erythrocyte sedimentation speed and increase in hemoglobin, in erythrocytes and in lymphocytes. The bacilli decrease, provided large doses of iodine are given; if small doses are given, this result is rare.

In purely fibrous and in productive cirrhotic forms without bacillary dissemination, small doses are sufficient. After ten injections it is advisable to interrupt the treatment for about two weeks and then repeat the series of injections several times. Most suitable are intravenous injections; but if the venous system is impaired, intramuscular injections may be given, which, however, are less readily tolerated by emaciated patients. In cavernous cirrhotic processes without marked dissemination of bacilli, the small doses are likewise sufficient. But if the bacillus content of the sputum is to be considerably decreased, larger doses are required. If caution is necessary, the same dose should be given several times in succession before it is increased. The decrease of the tubercle bacilli in the sputum cannot be considered a direct antibacterial iodine action, but it is probable that the iodine effects detoxication of the organism by binding the tuberculous toxins. By eliminating the paralyzing action of these toxins on certain cells, such as the leukocytes, lymphocytes, histocytes and epithelioid cells, the defense apparatus of the organism is mobilized, and thus a larger number of tubercle bacilli are destroyed.

Transitory, Inflammatory Pulmonary Infiltration of Nontuberculous Origin.—Boytinck discusses various forms of pulmonary infiltrations in which the source of infection and the blood picture do not indicate tuberculosis. He emphasizes that such infiltrations should be diagnosed as tuberculous only when every other etiology can be excluded or tuberculosis has been demonstrated. Nontuberculous infiltrations are especially frequent following nasal and pharyngeal disorders, but they are also observed after other infections, and they may even occur during pulmonary tuberculosis. The transitory character of such foci speak against tuberculosis, but even infiltrations of longer duration are frequently nontuberculous.

Nutritive Allergens.—On the basis of the clinical histories of two adult patients with lichen urticatus and with chronic urticaria with pigmentation, respectively, Urbach and Willheim call attention to the significance of sodium chloride, of organic acids and of sugars as nutritive allergens The detection of these connections is not only of theoretical interest; in the cases under discussion it showed the way to successful treatment, by which the patients were freed from allergic disorders to which they had been subject for years.

Thyroxine Therapy of Eclampsia and of Preeclamptic Disturbances.—Kustner bases his thyroxine therapy of eclampsia on the theory that an uncompensated hyperfunction of the posterior lobe of the hypophysis is an etiologic factor of eclampsia and also on the assumption of an antagonism between the posterior hypophysis and the thyroid. In his therapeutic experiences with thyroxine he found that of the three main symptoms of eclampsia, namely, increased blood pressure, retention of fluid and protein elimination in the urine, the fluid retention is most favorably influenced, in that the fluids are forced out of the tissues and into the blood stream and then are eliminated. For this reason thyroxine is most effective in the forms of eclampsia without high blood pressure but with considerable edema and a disturbed renal function. Still more effective than in eclampsia is the use of thyroxine in preeclampsia and in such conditions as dropsy and nephropathy. Here again the efficacy is most noticeable when the retention of fluid is the main symptom, but the thyroxine is ineffective when the blood pressure increase is most noticeable and the fluid retention is only slight. The author does not wish to overemphasize thyroxine therapy but only wants to point out that in many instances of eclampsia the administration of the secretion of the thyroid can be highly effective. He adds that large amounts of thyroxine do not exert an injurious effect on mother or infant.

Injection of Silver Preparations in Gonorrhea.—Lomholt thinks that the introduction of silver compounds into the urethra is still one of the most practical methods for the treatment of gonorrhea in men He assumes that its efficacy is due to a superficial caustic action by which the outer layers of cells are destroyed and the gonococci killed or their growth checked. But while exerting this action the silver is rapidly changed into silver chloride, which has only a small number of free silver ions and hardly any therapeutic effect In investigating as to what is the optimal length of time for which the silver preparation should be retained in the urethra, the author found that retention for from five to fifteen minutes, as is usually prescribed, is not necessary, since the chemical character and with it the therapeutic action of the silver compound change within less than a minute The rapidity of change varies in the different compounds In the case of silver nitrate, for instance, it was found that retention for from twenty to thirty seconds is sufficient, whereas other preparations can be retained for from forty to sixty seconds It was also observed that it is advisable to make several such brief injections immediately following each other, at least three each time, for otherwise one is not positive that the irrigation fluid has come in contact with the entire mucous membrane The treatment with three brief (twenty seconds each) successive injections should be given from three to four times daily The author found that this method is not only more agreeable to the patient but exerts action stronger than that of a single injection, lasting from five to fifteen minutes

New Roentgen Tube for Treatment of Uterine Tumors.—The attempt to treat tumors by introducing a roentgen tube into a body cavity, according to Schaefer and Witte, was tried more than twenty-five years ago. However, all the tubes that were constructed for this purpose proved unpractical until the authors, after their experiments with the cathode ray tube, tried to build a tube for introduction into body cavities. From a cathode ray tube that is of little therapeutic value they produced a roentgen tube by replacing the thin metal window by a thicker one that is not permeable for cathode rays, and thus it becomes an anticathode But since from such a tube the rays escape in all directions, it is not suited for use within a cavity. However, by shifting the ray source to the end of the tube, a radiation is produced that is similar to radium and has the advantage that by filtration the rays can be limited to the desired direction. After describing the structure of the apparatus, the authors advise as to how to introduce it into the vagina for irradiation of uterine tumors, and they state that the patients whom they treated with this method tolerated the irradiations well; neither roentgen intoxications nor burnings resulted Because of limited experience they do not feel justified in considering this the best method of irradiation, but they think that in certain cases it may improve the results

Bone Diseases in Women After Roentgen Treatment of Uterine Carcinoma.—Philipp calls attention to bone injuries, particularly to those of the neck of the femur, which have been observed in women following irradiation for uterine carcinoma. These bone injuries have been considered as of carcinomatous origin, but more careful observation revealed this assumption to be erroneous, and since the hip region of these women was subjected to intense irradiation the author suggests that the bone injuries may be the result of irradiation. He reviews several reports from the literature and describes several cases of his own observation The author examined his patients carefully for the presence of other disorders that might cause bone injuries, but he did not detect any. As an indication that the bone is injured directly by the rays and not by their general action, he cites the fact that in patients in whom the rays were not applied to the sides, but only to the abdomen and back, bone injuries as those described were not observed

Special Form of Urinary Retention and Its Treatment.—Lichtenstern and Marburg note that there are cases of incomplete evacuation of the bladder in which hypertrophic changes in the sphincter are thought responsible for the retention and which are therefore treated by a wedge-shaped excision from the sphincter. However, the authors found that this operation does not give the desired results, and that it is probable that this mechanical factor is not alone responsible for the deficient evacuation, but that the nervous apparatus also is involved They discuss the innervation of the bladder and describe the results of the neurologic examinations of their patients. The nervous symptoms were a hyperesthesia of the third, fourth and fifth sacral segments and increased patellar and achilles tendon reflexes. To overcome these functional disturbances, the patients were given injections of pilocarpine hydrochloride and epinephrine, at first every day and later every second day. After the tenth injection a considerable facilitation of the urinary evacuation was noted and the residual urine gradually decreased. After fifty injections the bladder could usually be completely evacuated This result, in connection with the neurologic observations and the inefficacy of the sphincterotomy, makes it probable that the inflammation caused a disturbance in the innervation of the bladder and that this in turn caused a disturbance in the sphincter and in the muscle facilitating the evacuation of urine. The so-called hypertrophy of the sphincter the authors consider as secondary, caused either by inflammation or by overburdening by the retained urine This makes it understandable why an excision from the sphincter does not produce the desired results.

Method of Determination of Beat Volume.—Hartl and Bonsmann say that until recently only gas analytic methods were known for the determination of the beat and minute volumes They review the physical methods that have been recommended With the method devised by Broemser and Ranke, they conclude that it is not only possible to confirm the results obtained with the gas analytic methods but also to estimate the slightest circulatory changes Broemser and Ranke's formula includes the following factors: duration of systole, duration of diastole, duration of pulse and the velocity of the pulse wave These factors can be determined from the pulse curves that are taken on the subclavian and the femoral veins But in addition to these factors the formula takes into consideration the density, that is, the specific gravity, of the blood, the blood pressure and a number factor, the latter being determined by comparison of the results obtained by a method devised by Broemser and of a gas analytic method that gives absolute values The authors discuss the results of their tests and present tables One table shows the circulatory changes in several persons in the course of a day. Following the intake of large quantities of fluid the minute volume is increased in normal persons, but in patients with circulatory disorders it may be decreased after meals. During upright posture there is a decrease in the circulatory factors and in the action of the heart The authors illustrate with tables the action of digitalis, caffeine, epinephrine, nonsurgical venesection, oxygen respiration, injection of a hypertonic solution of sugar or of an ergot preparation, and the influence of ether anesthesia.

Misuse of Tobacco and Hyperthyroidism.—According to Schlumm, the symptoms of chronic nicotine poisoning that have received the most attention are tremor of the hands, increased reflex irritability and inclination to tachycardia Some authorities think that these are of psychic nervous origin, whereas others noted a slight enlargement of the thyroid and consequently considered the possibility of an influence of nicotine on this organ In persons who consumed large amounts of tobacco the author nearly always noted damp skin, a tendency to sweating and to diarrhea, and occasionally also glossy eyes, decrease in weight and loss of hair. All these signs are symptomatic of increased action of the thyroid The blood picture of excessive smokers likewise resembles that of patients with exophthalmic goiter. These observations induced the author also to study the basal metabolism and he found that, of seventy-one persons who consumed excessive amounts of tobacco, fifty-five (more than 77 per cent) had increased metabolism. In those of the smokers who could be induced to abstain from tobacco, the basal metabolism decreased and the nervous symptoms likewise improved Further, the author studied the specific dynamic action of protein and also the iodine content of the blood. He found the latter to be considerably above the normal. He reaches the conclusion that the excessive use of tobacco, particularly of cigarets, has undoubtedly a considerable influence on the thyroid, and he thinks it probable that other incretory organs are likewise influenced, although so far studies have been made almost exclusively on the suprarenals, and some authors have suggested a connection between misuse of tobacco and certain disorders in the sexual apparatus.

Capillary Studies in Vascular Disturbances.—Zeitz-Kuckenburg describes capillaroscopic studies in vasoneuroses (migraine, urticaria, Quincke's edema, Raynaud's disease, sclerodermia) in peripheral arteriosclerosis and in thrombo-angiitis obliterans. The vasoneuroses show irregularity in the structure of the capillaries and changes in the direction of the current which correspond to the changes in the sympathetic functions and to the temporary character of the clinical manifestations. In peripheral arteriosclerosis, with or without gangrene, there are regularly elongated capillaries with thin arterial branches, and the hair-pin form predominates. In thrombo-angiitis obliterans the capillaries are characterized by the persistence of their form, width, number and arrangement. The development of gangrene produces no changes, and therapeutic measures influence only the current in the capillaries but not the form. This seems to indicate that in the vessels that are superordinated over the capillaries irreversible anatomic changes have taken place previous to the development of the gangrene, and these changes give the capillaries a definite, no longer reversible, form. On the basis of the typical capillaroscopic aspects, it is possible to differentiate vasoneurosis, peripheral arteriosclerosis and thrombo-angiitis obliterans, which in their early forms are difficult to diagnose. During the gangrenous stages, capillaroscopy aids in the diagnosis and gives etiologic pointers. Thus, capillaroscopy is a valuable method in the estimation of peripheral vascular disturbances.

Influence of Lecithin on Action of Insulin.—In experiments on rabbits as well as on human subjects, Skouge and Schrumpf were able to demonstrate that by simultaneous injection of insulin and lecithin the action of insulin is prolonged in comparison to pure insulin action. The subcutaneous or intravenous injection of lecithin alone causes no changes whatever in the blood sugar curve. However, the administration of lecithin alone, as well as the simultaneous administration of lecithin and insulin, causes a rapid but slight reduction in the blood pressure, which is probably due to an admixture of cephalin to the lecithin. When the insulin-lecithin mixture is administered intravenously, the resulting blood sugar curve does not differ from that which results from administration of insulin only. The effect of the prolonged action of insulin following subcutaneous administration of insulin and lecithin is due to a retardation in the resorption of the insulin. The same effect can be produced by subcutaneous injection of insulin in olive oil. The latter method of applying insulin is of therapeutic significance in cases in which it is desirable to avoid repeated injections in the course of the day. In this event the doses of insulin must of course be larger.

Self-Sterilization of Impregnated Catgut in Wound.—It is maintained by von Linden that sterility tests of impregnated catgut in bouillon correspond to the biologic conditions, and that catgut, the relative sterility of which has been proved by bouillon culture, never causes an infection. Then tests are described which she made to demonstrate the biologic aftersterilization in the living organism, and the efficacy of the impregnated catgut in preventing wound and general infections. The tests show that catgut impregnated with copper can be employed for suturing purposes without special precaution, since the biologic sterilization that takes place in the organism excludes the danger of infection. Copper catgut does not have to be protected either from septic material or from the air, because when it comes in contact with the body fluids it develops bactericidal powers. However, the author does not wish to advocate carelessness, for she thinks that double precautionary measures are always justified when health and life are at stake. By calling attention to the biologic sterilization of copper catgut, and to a lesser degree also of iodine catgut, she wishes to give to the surgeon a feeling of security.

Prophylaxis of Posttraumatic Meningitis.—According to Urech, meningitis is a frequent complication of injuries of the skull and in about 10 per cent of traumas of the skull it is the cause of death. If those who die from contusion of the brain during the first forty-eight or seventy-two hours following the trauma are excluded from the statistics, the morbidity and mortality from meningitis are still higher. Observations on posttraumatic meningitis convinced the author that it is usually fatal, that in a large percentage of cases it results from an infection of the ears and nose, that it may develop soon after the trauma, but also may be a late complication, and that as a rule it is caused by the pathogenic organisms that are usually found in the nose and ears, more particularly by streptococci and pneumococci. The occurrence of staphylococci is rarer and that of meningococci is exceptional. From these observations the author concludes that since posttraumatic meningitis cannot be cured, it should be prevented, and since the main pathogenic organisms are streptococci and pneumococci, a seroprophylaxis with the respective serums should be tried. Since the fall of 1927 he has given every patient with a cranial injury in addition to the usual antitetanus injection also one of antistreptococcus and antipneumococcus serum. Of the 168 persons with skull fractures who were treated in this manner, only one died as a result of a cerebral abscess containing staphylococci, and this abscess probably resulted from an infection of the trepanation wound. During the preceding four year period, before the seroprophylaxis was instituted, the fatalities following cranial fractures were in 21 per cent of the cases due to meningitis. The author also emphasizes that the seroprophylaxis never caused noticeable complications, and he recommends the treatment for further trial.

Influence of Sodium Formate on Gastric Secretion.—Riss states that deprivation of sodium chloride lowers gastric secretion and gastric acidity. Therefore a diet free from this salt is important in treating hyperacidity and ulcer with increased acidity. In his efforts to substitute a salt that would give the taste necessary to the food and yet not stimulate secretion, the author used sodium formate and also sodium acetate and sodium citrate. Experiments on dogs proved that these salts also increased gastric secretion and are therefore contraindicated in treatment with sodium chloride-free diets in gastric disturbances with hypersecretion and hyperacidity.

Hydrocephalus as Complication in Cerebrospinal Meningitis.—Rubinshtein states that hydrocephalus is one of the most frequent complications in cerebrospinal *meningitis* of children and that its occurrence does not depend on the severity of the primary infections. Among 322 patients with cerebrospinal meningitis examined during three and one-half years of study, 56, or 17.3 per cent, had hydrocephalus; and of the latter group, 21.4 per cent recovered, 50 per cent died, and 28.5 per cent were discharged with a tendency to chronicity. Specific symptoms for hydrocephalus are infrequent. The atypical forms of hydrocephalus are divided into (1) the abortive form with incomplete symptoms, (2) the latent form with late symptoms, (3) the form with symptoms simulating organic disturbances of the brain, and (4) the paroxysmal form. More than half the patients with hydrocephalus are nurslings; the incidence of hydrocephalus decreases as the age increases. The author discusses seven typical case histories and concludes that his study does not explain the reason for the appearance of hydrocephalus as a complication in cerebrospinal meningitis. He suggests early hospitalization of patients with cerebrospinal meningitis and systematic lumbar puncture together with specific serotherapy as prophylactic measures. Lumbar puncture seems to be the only method of treatment for hydrocephalus. The results are excellent in abortive forms, in latent forms with normal vision or accompanied by blindness, and also in subacute forms simulating organic disturbance of the brain and meninges. In hydrocephalus accompanied by encephalitis the benefits following lumbar puncture are doubtful; nor is it necessary to make a lumbar puncture in patients with protracted forms of the disease characterized by great volumes of edema fluid, large depressed fontanels and general hypotonia. Lumbar puncture in the latter condition may result in total collapse.

Intravenous Injections of Sodium Iodide in Treatment of Chronic Rheumatic Arthritis.—Snegurskiy states that according to the nomenclature worked out by the special commission on rheumatism that met recently at Moscow, rheumatic disturbances may be placed in one of two groups; namely, the acute group and the group including the chronic latent diseases with a variable etiology and pathogenesis and an uncertain nature. In the treatment of arthritis of the second group, the author used intravenous injections of sodium iodide. Freshly prepared 10 per cent solutions of sodium iodide were stored in dark glass bottles and the solutions were boiled before use. At the beginning, 10 cc. was injected into the vein with a 20 cc. syringe and, except when reactions were noted, the following injections consisted of 20 cc. of the same concentration of solution of sodium iodide. Injections were made at intervals of one, two and only exceptionally three days; the average number of injections was from ten to fifteen. In most patients the treatment caused no inconvenience outside of slight dizziness and nervousness; several patients experienced slight pain in the articulations several hours following treatment and only one patient had a strong reaction, which was characterized by headache, a rush of blood to the head, restlessness, perspiration, and abundant secretion of mucus. Among forty-seven patients treated, thirty-eight had beneficial and nine had negative results. Some of the patients of the last group probably had podagric forms of arthritis, which do not react to injections of sodium iodide; some of these were unusually excitable and the nervous state was aggravated by pain. The author adds that sodium iodide is efficacious in neglected cases of arthritis in which other treatment has failed. In some instances the injections can be accompanied by other measures of treatment, especially physical therapy.

Bang's Bacillus Infection of Man.—Kushelevskiy states that malta fever due to Brucella melitensis is a disease of small horned cattle of southern and subtropical climates, whereas Brucella abortus infects large horned cattle and swine of a more northerly climate. In animals, the infection has an affinity for the genitalia, leading to abortion in the female, affecting the testes in the male, and causing sterility in both. Brucella melitensis is an obligatory, while Brucella abortus is a facultative pathogen for man. Infection in man is a result of contact with animals and especially through the use of raw milk and various milk products. Men are more susceptible to the disease than women, and the incidence is greatest in the age group from 20 to 40. The incubation period in several laboratory infections was from two to three weeks (in professional infection this period is shorter). The clinical picture is characterized by a remittent or intermittent fever with enlargement of the spleen and the liver, malaise, slight headache, perspiration and febrile remissions. The symptoms are even less marked than those in typhoid. The presence of frequent and typical complications of the sacral region, various skin eczemas and erythemas, articular complications (arthralgia and serous and suppurative arthritis) are more marked in Bang's disease than in malta fever. Bang's disease may also be accompanied by orchitis and orchiepididymitis with great pain and periodic swelling of the testis. The influence of Bang's infection on abortion in women is not definite. One writer reports seven abortions among eight gravidas with Bang's infection. The infection lasts from three to five months, while subchronic forms last a year and longer. The undulating character of the fever is not as distinct as in malta fever. The disease should be distinguished from typhoid and also latent miliary tuberculosis, various septic processes, colibacillary sepsis, malaria and rheumatic infections. Prognosis is usually favorable. There is no specific therapy except those medicaments indicated in septic infections (intravenous injections of quinine, colloidal silver, and neoarsphenamine alone or combined with methenamine).

Inversion of Uterus and Adherent Placenta. T. Gedde-Dahl.—p. 660.
*Low Duodenal Stenosis. J. Frimann-Dahl.—p. 664.

Roentgenograms of Pyloric Hypertrophy and Prepyloric Spasms.—Serck-Hanssen presents roentgenograms which show large blank patches in the contrast shadow corresponding to the distal part of the pyloric canal. As in cancer, the defect may be constant on repeated roentgen examination at intervals of some weeks and peristalsis may cease in the part corresponding to the defect. Operation in three cases revealed chronic gastritis without ulcer and, in one case, chronic gastritis with ulcer in the lesser curvature. In two cases with resection for chronic gastritis, considerable hypertrophy of the pylorus was found; in the roentgenograms this was evidenced by the great distance between the otherwise well filled pyloric canal and the well filled duodenum.

Spontaneous Rupture of Aorta.—Treider reports the case of a man, aged 48, previously well, in whom there occurred, without external cause, rupture of a dissecting aneurysm of the aorta with massive hemorrhage into the left pleural cavity. Gradually the aneurysm filled with fibrin and clotted blood and the patient improved somewhat. A second rupture then took place, with hemorrhage of over 3 liters, and immediate death. Necropsy showed total necrosis in the media, especially marked at the places of rupture. There were no signs of syphilis or other inflammation, only atheromatous changes. The primary cause of the necrosis is thought to have been toxic substances with epinephrine-like action and point of attack in the vasa vasorum.

Influence of Mersalyl on Glycosuria.—Sinding-Larsen's investigations confirm the results first described by Blix and Wechsler, that mersalyl reduces the glycosuria in diabetes, with simultaneous increase in the blood sugar, but does not affect the blood sugar in persons without glycosuria. He thinks the effect depends on a raised kidney threshold and is difficult to explain without accepting the filtration theory.

Low Duodenal Stenosis.—Frimann-Dahl describes three cases of duodenal stenosis in which diagnosis was established by roentgen examination and verified on operation, in one case also on necropsy. In all cases the roentgenograms disclosed a dilatation of the duodenum of fully the size of the fist, with stenosis peristalsis and retention in the distended portion after four and a half hours. In the first case a diverticulum was found on operation and on necropsy, in the second, in addition to the dilated duodenum, there was a peculiar hypertrophy of the upper jejunum thought possibly to be of congenital origin, and in the third operation revealed a small adhesion which might have caused the stenosis.

DEHYDRATION ATTENDANT ON SURGICAL OPERATIONS

FREDERICK A. COLLER, M.D.
AND
WALTER G. MADDOCK, M.D.
ANN ARBOR, MICH.

Water is the principal constituent of the body and is essential to the life and activity of every cell. In conditions of health a person automatically cares for his water needs through response to hunger and thirst; in conditions of disease the water supply is frequently governed by the physician. To care for these important water requirements intelligently requires a knowledge of the water losses and gains under all circumstances connected with disease. This study was undertaken to evaluate the water losses of the body during operation and in the recovery period of four hours after operation.

Water, comprising 70 per cent of the body weight, is ingested in greater amounts than all other substance combined. It is importantly concerned with the excretion of waste products and the dissipation of heat. In health the body holds a fixed amount of water and excretes whatever water is excessive. The study of this water balance necessitates the determination and calculation of the four sources of water to the organism and the three sources of excretion of water from it. The factors involved in water balance are as follows:

Intake	Output
1. Water of food.	1. Water of urine.
2. Water drunk.	2. Water of stool.
3. Water of oxidation.	3. Insensible water.
4. Preformed water.	

INTAKE

1. The amount of water in ordinary solid food is comparatively high. Meats run over 50 per cent water content, while vegetables and fruit are generally above 75 per cent water. The regular house diet in the University Hospital yields about 1,000 cc., and the soft diet has a water content of about 500 cc. of water a day. This source is therefore a real but varying percentage of the total water intake.

2. The average daily intake of fluids drunk varies greatly from day to day. Atwater and Benedict[1] found totals of from 833 to 1,407 cc. with the subject during light activity, averaging 1,267 cc. for forty-nine days. With increasing work the average amount ingested rose to 2,045 cc. For general considerations one may take about 2,000 cc. as the average adult intake.

3. Water is formed by the oxidation of the hydrogen of the foodstuffs in proportion to the amount of these materials consumed. The total amount is proportional to the total metabolism and is in the neighborhood of 300 Gm. for persons at light activity.

4. The preformed water is the body water that is attached to the tissues in the normal manner and is set free when tissue is oxidized. Similarly deposition of new tissue is attended by the retention of a corresponding amount of water. This amount is ordinarily so small as to have no important bearing on the total water balance, but in starvation may reach a value of 250 Gm. per day.

OUTPUT

1. In general, the amount of urine voided varies from 800 to 3,000 cc. daily. The weight of the urinary solids may be determined if accuracy is desired.

2. Water loss in feces of normal man is generally not more than 200 cc., usually between 60 and 150 cc. daily.

3. There is a continuous insensible loss of water from the skin and lungs that is always a large amount and may be the greatest increment of outgoing water even under normal conditions. The insensible loss of weight is made up largely but not entirely of water vapor. The body is continuously giving off water and carbon dioxide. The sum of these two obviously results in a progressive loss of weight which is slightly counterbalanced by the simultaneous absorption of oxygen. The relationship may be conveniently expressed as an equation, thus:

$$\text{I. L.} = H_2O\ \text{vapor} + CO_2 - O_2$$

or

$$\text{I. L.} - (CO_2\text{-}O_2) = H_2O\ \text{vapor.}$$

The actual determination of the insensible loss (I. L.) carbon dioxide (CO_2) and oxygen (O_2) by Wiley and Newburgh[2] showed that the water vapor varies from about 85 to 100 per cent of the total insensible loss. Generally it is well over 90 per cent. The conditions under which we worked did not permit such an analysis of the loss by our patients, but it is safe to assume that about 95 per cent of the weight thus lost in the operating room is water. Newburgh, Wiley and Lashmet[2b] studied the insensible loss in eight persons at normal activity over long periods of time and found this daily water loss to average from 1,000 to 1,550 cc. To this insensible loss a considerable amount may be added by the running away of sweat.

From the Department of Surgery, University of Michigan.

Read before the Section on Surgery, General and Abdominal, at the Eighty-Third Annual Session of the American Medical Association, New Orleans, May 12, 1932.

H.; Wiley, F. H., and Lashmet, F. H.: A Method for the Determination of Heat Production Over Long Periods of Time, ibid. **10**: 703 (Oct.) 1931.

Increased metabolism or an uncomfortably high environmental temperature will increase the insensible loss.

In conditions of disease, when it is so important to maintain normal body water, it is often difficult to establish a sufficient inflow, because patients commonly refuse or are forbidden food and drink. Water may be conserved by the kidneys putting out as highly a concentrated urine as possible. This, however, may not be in sufficient quantity to get rid of the ordinary excretory substances, so that retention of nitrogenous and other waste material may occur. Instead of the normal insignificant loss of water from the gastrointestinal tract, diarrhea and vomiting may result in great losses. As shown by Orr and Haden[3] and Gamble and his colleagues,[4] the loss of water in this manner is accompanied by a serious loss of the sodium and of the chlorides it contains. Through this whole period, the insensible loss of water continues in spite of the curtailed intake. Fever, by increasing the metabolism, increases the insensible loss. The sweating of patients in the operating room and during the period of immediate recovery causes a further great outpouring of water. The study undertaken to evaluate the factors of fluid loss during this period was carried out as follows:

Table 1.—*Major Calculations for One Patient, Showing Method Used*

	Operation Period		
Patient no. 9—Partial gastrectomy for carcinoma Height, 66 inches. Body surface area, 1.57 sq. meters			
9:40 a.m.	Weight of patient		51,125 Gm.
9:45 a.m.	Anesthetic started, nitrous oxide and oxygen plus ether vapor		
11:48 a.m.	Anesthetic ended, moderate diaphoresis		
12:03 p.m.	Weight of patient and dressings.	50,305 Gm.	
	Corrections to be added		
	Weight of vomitus	37 Gm.	
	Weight of specimen	127 Gm.	
	Weight of blood lost	277 Gm	
		50,746 Gm.	
	Corrections: to be subtracted		
	Weight of dressings	181 Gm.	
			50,565 Gm
Weight of insensible loss plus moderate visible sweating In grams per square meter of body surface per hour, 149 8			560 Gm
	Postoperative Period		
12:03 p.m.	Weight of patient and dressings		50,305 Gm.
4:12 p.m.	Weight of patient and dressings.	51,761 Gm	
	Correction to be subtracted		
	Subpectoral infusion 5 per cent dextrose	1,746 Gm.	
	(No vomitus, no urine voided)		50,015 Gm
Weight of insensible loss plus slight visible sweating In grams per square meter of body surface per hour, 44 5			290 Gm.

The patient urinated just before leaving the ward. In the anesthetizing room, measurements of the skin temperature were taken. The top of the transporting stretcher coud be lifted off as a flat pan. The pan, patient and covers were then weighed on a platform scale accurate to 5 Gm. The patient was shifted to the operating table, and a new gown and covers were applied. The pan and the original covers were then weighed, in order to obtain the weight of the patient. During the course of the operation, measurements of the skin temperature were made. The temperature and humidity of the operating room were taken several times and averaged for the period. The weight of the vomitus, all tissue removed, the fluid taken up by the aspirator and the dressings used was carefully noted. The amount of blood lost during the operation was determined by the method of Gatch and Little.[5] At the end of the operation, all visible perspiration on the patient's body was wiped off and a dry gown and blanket were applied. The patient was shifted to the stretcher and the weight of the patient determined. The water exchange of the patient was followed in a similar manner for the immediate postoperative recovery period of four hours. A typical example of the major calculation for one patient is shown in table 1. The results of this study on eighteen patients during operation are shown in table 2.

For purposes of discussion, the cases may be divided into two groups, the first comprising cases 1 to 12, inclusive, which were studied under conditions of operating room routine with the usual coverings of a light blanket over the shoulders and thorax of the patient, another over the legs, a cotton shirt, leggings and surgical drapes. The second group comprised cases 13 and 18, inclusive, with a covering only of a shirt, leggings and drapes.

The water loss due to vomitus obviously will vary greatly with many factors of anesthesia and the patient's lesion. In the patients observed, the water lost from vomiting was small, and in no instance was it a factor of importance in the total outgo of water. It is obvious, however, that in patients with acute lesions of the abdomen such as intestinal obstruction the water loss from vomiting might be enormous. An accurate knowledge of the amount would be imperative to a proper maintenance of the water balance.

The blood loss as given in the figures is probably from 5 to 10 per cent less than the actual amount because of the inability to recover all of the hemoglobin from the sponges, drapes and instruments. These amounts are in accord with those published by Gatch and Little.[5] In most cases the amount of blood lost is not great and does not have a marked influence either on the fluid balance of the body or on the total blood volume. In general, the operator is surprised to find the blood loss as high as calculated, since he does not think of the gauze sponge as absorbing much blood. In one instance (case 8), a large, obese woman on whom a radical amputation of the breast for carcinoma was performed, there was a large loss of blood amounting to 1,272 Gm. This blood loss was not due to any one violent hemorrhage, but to many small venous hemorrhages that were absorbed rather than stopped by gauze packing. This patient had mild postoperative shock undoubtedly due to the loss of blood. It is probable that most surgeons underestimate the amount of blood lost, especially in operations such as the one mentioned, in which wide areas of the body are uncovered with many small points of hemorrhage, control of which is attempted by gauze packing. A rough estimate of the blood lost in any operation can undoubtedly be made and should be calculated as part of the total fluids lost by the body during this period, even though the blood loss alone is not regarded as serious in itself.

The water lost from the skin and lungs during the operative period is not usually appreciated and yet, as can be seen, may be a large amount. The total water lost during operation in this manner varied from 97 to 705 Gm., in general being a loss of fluids much in excess of the blood lost. In order to obviate the differences of time and the size of the patient, the insensible loss and the visible sweating were computed to the accepted standard of water in grams per square meter of body surface per hour. Wiley and Newburgh[2a] reported the normal for a subject under basal conditions to be from 17 to 21 Gm. of insensible water per square meter per hour. A comparison of this figure with those shown in the last column of table 2 demonstrates that the water loss by this method is much increased over the normal and may be as high as from eight to nine times as much as that for a patient at rest in bed.

[5] Gatch, W. D., and Little, W. D.: The Amount of Blood Lost During Some of the More Common Operations, J. A. M. A. **83:** 1077 (Oct 4) 1924.

The factors that produce this great increase of insensible loss and visible sweating are probably many and hard to deal with individually, but the total loss is the significant point.

Environmental temperatures above 27 C. (80.6 F.) were usually accompanied by a higher insensible and sweating loss. A comparison of case 1 with cases 2 and 3 shows a greater water loss with a higher temperature in the operating room, but other factors make comparison difficult. No constant effect of variation in humidity within the ranges observed was noted in these patients.

In the second group of patients, cases 13 to 18, a reduction in covering while under the anesthetic resulted in general in a definite reduction of the water losses. All of these facts are in accord with the findings of Wiley and Newburgh.[2a] The constant temperature of the body is maintained by a balance of the heat production with the heat loss through radiation, conduction and convection and by the vaporization of water. From a temperature of from 18 to 27 C., the body temperature is maintained largely by radiation, with about 24 per cent lost by evaporation. With an environmental temperature above 27 C., the heat lost by vaporization increases rapidly with utilization of the sweat mechanism. The water losses increase rapidly with each rise in temperature of 1 degree after this point. Since in the clothed subject the insensible loss is not affected by humidity, the patient wrapped in blankets is not thus affected by the humidity of the operating room. A patient under blankets or a person with clothing lives in his own environment, which is influenced somewhat by the temperature around it. If the coverings are excessive, the temperature of this environment will reach the temperature of the body, and efforts at heat loss will cause vasodilatation and marked sweating. A reduction in the covering permits a greater heat loss by radiation and diminishes the loss of water by vaporization.

It was noted that straining and moving under the anesthetic were associated with greater sweating than when the patient was quiet. This phenomenon frequently became evident immediately at the onset of straining. This point is well shown by cases 1, 2, 3 and 12, in which avertin was used, compared with cases 4, 6 and 9, in which ether was added to nitrous oxide and oxygen to secure relaxation. As has been frequently shown,[6] general inhalation anesthesia and spinal anesthesia produce peripheral vasodilatation, which was noted in all of our cases. This vasodilatation interferes with the normal mechanism of heat loss.

The largest insensible and visible sweat loss was in case 8, that of a large, obese woman in moderate shock. The association of marked sweating with surgical shock is often noted and, if present, is another factor increasing the loss of water. In cases 13 to 18 blankets were omitted from the covering while the patients were in the operating room with, in general, a diminution of the amount of water loss. The number of cases studied, however, is too small to permit of any generalization in regard to this point.

The total fluid loss during the operation varies with the type of operation, the length of the operation and a number of variable factors of the temperature, anesthesia, covering and condition of the patient. It is small, between 100 and 200 Gm., for short operations such as herniorrhaphy and appendectomy. For larger operations of a moderate severity, the total fluid loss will average about 500 Gm., and in prolonged operations with a marked blood loss, it may reach 1 or even 2 liters.

The water lost during the recovery period of four hours after operation is shown in table 3. The water lost by vomitus was absent or very slight. The principal excretion was by the insensible loss plus visible sweating. The patients in cases 1 to 12 were placed in bed, with the routine covering of a spread, woolen blanket, sheet, woolen blanket, flannel blanket and gown. In one instance, case 5, the water loss was 828 Gm., probably due to marked sweating. In the other cases the water loss was from 217 to 450 Gm. In cases 13 to 18 the covering was reduced to a spread, woolen blanket, sheet and gown, with a noticeable diminution of the water lost through the skin and lungs. The water then lost varied from a minimum of 126 Gm. to 286 Gm. The contrast is sharpened by comparing this loss as expressed in grams per square meter per hour in the two groups. The patients with the lighter covering were much more comfortable and lost on an average of 200 Gm. of water during the four hour period less than those with heavier covering. We can see no logical reason for the excessively heavy covering often used for the patient during the recovery period.

In order to compare the total fluid lost during the entire period of operation and the four hours after operation with the amount of urine excreted during this time, the patients voided or were catheterized after the last weighing. The results are shown in table 4, with the amount of urine excreted expressed in quantity and in terms of percentage of the total fluid loss. In the first twelve cases the urine output is less than 15 per cent of the total water lost during the entire time. In the last six patients the urine output rose to from 22 to 50 per cent of the total fluid loss. The total fluid lost during the period of operation and recovery by a patient on whom a laparotomy is performed will average close to a liter. Much greater losses occurred in certain cases in which there was marked sweating or blood loss. The component parts of the total loss are shown in the accompanying chart, emphasizing the relative importance of the insensible loss. The much greater amount of fluid lost by avenues other than the kidneys makes it clear that the commonly accepted clinical method of estimating the water balance by a comparison of the fluid intake with the urinary output is so inaccurate as to be worthless to the patient for whom an accurate maintenance of the water balance is necessary. We recognize the value of the specific gravity of the urine in giving an idea of the state of the water balance, granting that the concentrating power of the kidneys is normal or known. It is customary in many hospitals to chart graphically the fluid intake against the urinary output. The information thus obtained is adequate for the care of the ordinary patient operated on, but it does not represent the true water balance, as from 1,500 to 2,000 Gm. or more of insensible water may be lost by the patient in bed with fever. The body will still vaporize water in about the same amount to remove its heat even when the supply of water is so seriously diminished that anuria supervenes. There are certain sick patients undergoing operations in whom it is all important to maintain a proper supply of water. This can be done only by taking into account the water lost through the skin and lungs, vomiting and diarrhea, as well as that excreted through the kidneys.

TABLE 4.—*Comparison of Urine Output to Total Fluid Loss During Operative and Four Hour Postoperative Period*

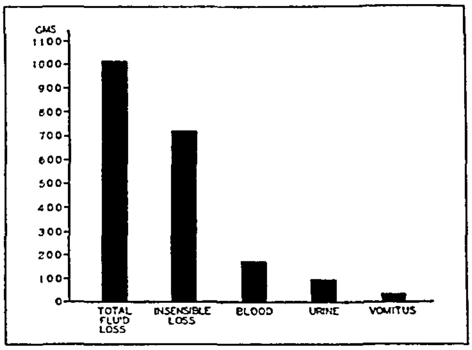
18	473	163	25.63

Insensible water contains negligible amounts of inorganic salts, and in the amounts of water lost in these patients, the salt loss is not important in contradistinction to the fluid lost by vomiting, diarrhea or enterostomy, in which the inorganic salt is so important. Therefore, normal dextrose solution can be used to replace this component of the body fluids. The fact that the water lost by evaporation [2a] increases rapidly with the rise in environmental temperatures beyond 27 C. should make one inquire seriously as to whether it is wise to subject the patient, during the postoperative period, to such high environmental temperatures as are usually caused by excessive bed clothing.

SUMMARY



Components of average total fluid loss during operative period and four hour postoperative period.

1. A study was made of eighteen patients on whom operations were performed to determine the body fluid lost during the operation and during the first four hours after operation.

2. During operation fluids were lost by vomitus, hemorrhage and insensibly through the skin and lungs. The amount lost by vomitus was not important; the amount lost by hemorrhage is often greater than the surgeon believes and varied with the type of operation from 8 to 1,272 Gm. The insensible loss plus visible sweating varied from 97 to 705 Gm., while this loss expressed in grams per square meter per hour is increased as high as nine times that of the basal state.

3. During the first four hours after operation the principal water loss was through the lungs and skin, varying from 126 to 828 Gm. A comparison was made between two groups with different bed clothing. The water loss of the patients with lighter bed clothing was over 50 per cent less than that of the group placed in the routine "ether bed."

4. The factors increasing the insensible loss and sweating were the temperature of the environment, principally that produced by blankets, struggling under anesthesia and the anesthetic.

5. Under routine conditions, the total loss during the entire period averaged about 1 liter. It may be much higher in certain instances. The urinary output during this period averaged less than 10 per cent of the total fluid lost. A comparison of the urinary output with the fluid intake does not give a correct estimate of the water balance. Other factors of water loss such as vomiting and diarrhea are important and have been stressed. We wish here to emphasize another important source of water loss amounting to from 1½ to 2 liters a day by the continuous insensible vaporization from the lungs and skin.

ABSTRACT OF DISCUSSION

Dr. Thomas G. Orr, Kansas City, Mo.: Food and water, of course, may be taken by the average patient up to within a few hours prior to an operation. Certainly it is not necessary in the average case to give any cathartics at any time prior to the operation. One conserves the patient's water in anticipation of the insensible loss that must inevitably occur in a high percentage of the patients who are given ether anesthesia. The chief concern when considering this insensible loss of water, is in those patients who are greatly depleted before reaching the operating room, and in preparing these patients one must provide for this loss as well as for the loss occasioned by the lack of water and the lack of food. In other words, it is necessary to consider carefully the water balance and the metabolic balance and the chemical balance in this class of patients before one proceeds to do an operation. The results of dehydration are far reaching if the dehydration is extreme. There is a disturbance of the heat regulating mechanism, an increase of the viscosity of the blood, a decrease in the oxygen carrying capacity of the blood, a decrease in the kidney function, and a disturbance of the acid-base balance. All these may be of extreme importance, of course, if the dehydration proceeds to an advanced degree. A compilation by Dr. Rowntree a number of years ago showed the intake of secretions into the upper intestinal tract in a period of twenty-four hours. The intake of saliva, bile, gastric juice, pancreatic juice and the succus entericus into the upper intestinal tract, in other words, an intestinal circulation, which takes place every twenty-four hours, amounts to an astonishing quantity compared to the quantity of blood in the body. The daily secretion into the upper gastro-intestinal tract amounts to between 7 and 8 liters. This represents two or three times the average quantity taken by mouth in twenty-four hours, three or four times the quantity of urine excreted, and about twice the total volume of the blood of the body. One can readily appreciate the importance of this internal gastro-intestinal, tract circulation. Any disturbance of this circulation must necessarily upset the metabolism of the tissues. It is this point that I wish to emphasize. I recommend, therefore, that the members of this group give this paper further study when it has been published, and I further suggest, if they have not already done so, that they review the classic articles by Rowntree and Marriott; Rowntree on "Water Balance," Marriott on "Anhydremia," which have been published in *Physiological Reviews*. Every operator doing major surgery should familiarize himself in a general way with the water and chemical balance of the body before undertaking a difficult type of operation.

Dr. Isidore Cohn, New Orleans: The authors properly emphasize the loss of water by sweating during operation in patients who are covered or overcovered. Interesting experiments prove that the loss is greater in the patients who are covered by too many blankets. They further emphasize that the amount of blood that is lost is oftentimes greater than is realized by the surgeon. It is proper to emphasize these things but I do not believe that the importance of having the patient at least properly covered should be forgotten or overlooked because the lowering of the general body temperature may have more effect on the patient than the insensible loss of water through the lungs and by sweating. It should also be remembered that the insensible loss can be guarded against by preoperatively increased fluid intake. Vomiting can be diminished by postoperative administration of fluids by other than the oral route.

Dr. G. A. Hendon, Louisville, Ky.: Loss of heat can be avoided to a large extent by a simple procedure. After the abdomen is opened, if there is, in the judgment of the surgeon, an extensive operation in prospect, he can clip off the distal end of the appendix, cut and tie the meso-appendix, and insert a catheter with two or three sutures through it and the appendix to hold it in place; he can then fill the colon with water at any desirable temperature, which gives an internal hot-water bag. This measure can be pursued in the patient's bedroom and the water changed as it becomes cooler, and more warm water supplied. This will compensate for the loss of both heat and water, and the appendix will slough off in about one week. In no case have I seen a fistula result.

Dr. J. Shelton Horsley, Richmond, Va.: The authors call attention to a phenomenon that is frequently overlooked.

amount of water loss. The number of cases studied, however, is too small to permit of any generalization in regard to this point.

The total fluid loss during the operation varies with the type of operation, the length of the operation and a number of variable factors of the temperature, anesthesia, covering and condition of the patient. It is small, between 100 and 200 Gm., for short operations such as herniorrhaphy and appendectomy. For larger operations of a moderate severity, the total fluid loss will average about 500 Gm., and in prolonged operations with a marked blood loss, it may reach 1 or even 2 liters.

The water lost during the recovery period of four hours after operation is shown in table 3. The water lost by vomitus was absent or very slight. The principal excretion was by the insensible loss plus visible sweating. The patients in cases 1 to 12 were placed in bed, with the routine covering of a spread, woolen blanket, sheet, woolen blanket, flannel blanket and gown. In one instance, case 5, the water loss was 828 Gm., probably due to marked sweating. In the other cases the water loss was from 217 to 450 Gm. In cases 13 to 18 the covering was reduced to a spread, woolen blanket, sheet and gown, with a noticeable diminution of the water lost through the skin and lungs. The water then lost varied from a minimum of 126 Gm. to 286 Gm. The contrast is sharpened by comparing this loss as expressed in grams per square meter per hour in the two groups. The patients with the lighter covering were much more comfortable and lost on an average of 200 Gm. of water during the four hour period less than those with heavier covering. We can see no logical reason for the excessively heavy covering often used for the patient during the recovery period.

In order to compare the total fluid lost during the entire period of operation and the four hours after operation with the amount of urine excreted during this time, the patients voided or were catheterized after the last weighing. The results are shown in table 4, with the amount of urine excreted expressed in quantity and in terms of percentage of the total fluid loss. In the first twelve cases the urine output is less than 15 per cent of the total water lost during the entire time. In the last six patients the urine output rose to from 22 to 50 per cent of the total fluid loss. The total fluid lost during the period of operation and recovery by a patient on whom a laparotomy is performed will average close to a liter. Much greater losses occurred in certain cases in which there was marked sweating or blood loss. The component parts of the total loss are shown in the accompanying chart, emphasizing the relative importance of the insensible loss. The much greater amount of fluid lost by avenues other than the kidneys makes it clear that the commonly accepted clinical method of estimating the water balance by a comparison of the fluid intake with the urinary output is so inaccurate as to be worthless to the patient for whom an accurate maintenance of the water balance is necessary. We recognize the value of the specific gravity of the urine in giving an idea of the state of the water balance, granting that the concentrating power of the kidneys is normal or known. It is customary in many hospitals to chart graphically the fluid intake against the urinary output. The information thus obtained is adequate for the care of the ordinary patient operated on, but it does not represent the true water balance, as from 1,500 to 2,000 Gm. or more of insensible water may be lost by the patient in bed with fever. ABSTRACT OF DISCUSSION

Dr. Thomas G. Orr, Kansas City, Mo.: Food and water, of course, may be taken by the average patient up to within a few hours prior to an operation. Certainly it is not necessary in the average case to give any cathartics at any time prior to the operation. One conserves the patient's water in anticipation of the insensible loss that must inevitably occur in a high percentage of the patients who are given ether anesthesia. The chief concern when considering this insensible loss of water, is in those patients who are greatly depleted before reaching the operating room, and in preparing these patients one must provide for this loss as well as for the loss occasioned by the lack of water and the lack of food. In other words, it is necessary to consider carefully the water balance and the metabolic balance and the chemical balance in this class of patients before one proceeds to do an operation. The results of dehydration are far reaching if the dehydration is extreme. There is a disturbance of the heat regulating mechanism, an increase of the viscosity of the blood, a decrease in the oxygen carrying capacity of the blood, a decrease in the kidney function, and a disturbance of the acid-base balance. All these may be of extreme importance, of course, if the dehydration proceeds to an advanced degree. A compilation by Dr. Rowntree a number of years ago showed the intake of secretions into the upper intestinal tract in a period of twenty-four hours. The intake of saliva, bile, gastric juice, pancreatic juice and the succus entericus into the upper intestinal tract, in other words, an intestinal circulation, which takes place every twenty-four hours, amounts to an astonishing quantity compared to the quantity of blood in the body. The daily secretion into the upper gastro-intestinal tract amounts to between 7 and 8 liters. This represents two or three times the average quantity taken by mouth in twenty-four hours, three or four times the quantity of urine excreted, and about twice the total volume of the blood of the body. One can readily appreciate the importance of this internal gastro-intestinal, tract circulation. Any disturbance of this circulation must necessarily upset the metabolism of the tissues. It is this point that I wish to emphasize. I recommend, therefore, that the members of this group give this paper further study when it has been published, and I further suggest, if they have not already done so, that they review the classic articles by Rowntree and Marriott; Rowntree on "Water Balance," Marriott on "Anhydremia," which have been published in *Physiological Reviews*. Every operator doing major surgery should familiarize himself in a general way with the water and chemical balance of the body before undertaking a difficult type of operation.

Dr. Isidore Cohn, New Orleans: The authors properly emphasize the loss of water by sweating during operation in patients who are covered or overcovered. Interesting experiments prove that the loss is greater in the patients who are covered by too many blankets. They further emphasize that the amount of blood that is lost is oftentimes greater than is realized by the surgeon. It is proper to emphasize these things but I do not believe that the importance of having the patient at least properly covered should be forgotten or overlooked because the lowering of the general body temperature may have more effect on the patient than the insensible loss of water through the lungs and by sweating. It should also be remembered that the insensible loss can be guarded against by preoperatively increased fluid intake. Vomiting can be diminished by postoperative administration of fluids by other than the oral route.

Dr. G. A. Hendon, Louisville, Ky.: Loss of heat can be avoided to a large extent by a simple procedure. After the abdomen is opened, if there is, in the judgment of the surgeon, an extensive operation in prospect, he can clip off the distal end of the appendix, cut and tie the meso-appendix, and insert a catheter with two or three sutures through it and the appendix to hold it in place; he can then fill the colon with water at any desirable temperature, which gives an internal hot-water bag. This measure can be pursued in the patient's bedroom and the water changed as it becomes cooler, and more warm water supplied. This will compensate for the loss of both heat and water, and the appendix will slough off in about one week. In no case have I seen a fistula result.

Dr. J. Shelton Horsley, Richmond, Va.: The authors call attention to a phenomenon that is frequently overlooked.

In the average surgical case, considerable amounts of fluid are lost, but in the average case the biologic mechanism works while we sleep, so that the loss is not usually felt. It is in the rather unusual case, the depleted case, the case of sepsis, the bad risk case, that this loss may turn the scale. The loss of heat, of course, has to be considered as well as the loss of water. Though not directly applicable to this discussion, the temporary loss of fluids, such as in shock, in spinal anesthesia, sometimes may occasion grave concern. This loss may be compensated for by natural methods, but the ordinary means of absorbing fluids are at least handicapped if not entirely abolished in many abdominal conditions. The patient may have peritonitis, obstruction or a gastric or intestinal operation in which the natural means of absorbing fluids are temporarily closed. The patient in shock or who has lost a large amount of blood is incapable of absorbing water from the intestine to any considerable extent. Dr. Matas called attention to a method of supplying fluids which will not only give abundant amount of fluid but give it without straining the function of the gastrointestinal tract, which in abdominal operations at any rate should have physiologic rest. That is the intravenous method introduced ten or twelve years ago, in which dextrose is given continuously into the vein. This method has been modified by Drs. Hendon, Gallie, Harris and others. Usually I give 5 per cent dextrose in normal Ringer's solution. It supplies not only an isotonic solution of dextrose but the ordinary electrolytes, not only sodium chloride but potassium and calcium as well. In spinal anesthesia, which I use occasionally, I have adopted the method of beginning the intravenous administration of fluid at the same time that the spinal anesthesia is begun through a needle or a cannula. It can be turned on in greater volume when the blood pressure goes down alarmingly, or it may be continued at a slow rate

Dr. Frederick A. Coller, Ann Arbor, Mich.: Those who have discussed the paper have added much that is practical. I did not mean to imply in the paper that the exact computations that were carried out are necessary to the well-being of every patient. Most surgical patients have been getting well for many years on the usual regimen, and if one will give a pitcher of water to a patient with a normal gastro-intestinal tract he will automatically maintain his water balance. On the other hand, this information may be of some importance to the very sick patient. I think one can give it as a safe general rule that if 2.5 liters is allowed for the first day, including the time of operation, and 2 liters a day from that time on, it will represent the amount of water being lost by the body through the lungs and the skin. If one wants to wash out toxins or do anything else with the water, one must use it in quantities above that amount. The amount of water that it is desirable to give to the surgical patient falls outside the scope of this discussion and is not touched on in this paper.

Essential Qualities of Research Workers.—Research workers must have imaginative minds and natural powers of observation. The essential qualities to be looked for in a research man are honesty, common sense, balanced enthusiasm, self-confidence, tenacity, system and method in keeping notes and in planning and carrying out experiments, and unreserved devotion to the problem in hand. If a man is not honest he may deceive himself and be led to draw conclusions from false results which will not stand repetition by other workers. If a man lacks common sense he is liable to be easily side-tracked, and is led to do foolish things in the name of research. If a man does not possess enthusiasm, he very soon becomes lazy and gambles away his time, but if he becomes overenthusiastic he may become carried away and arrive at conclusions too hastily. If he lacks self-confidence, he can never convince himself or others of the value of his work. The young worker must not become discouraged even if the trend of experiment goes against theory. If he has not the tenacity to continue he will often miss out and, because of incompleteness, his work will fail. The research man who lacks method and system is like a ship without a rudder. The young worker who has not an unreserved devotion for his work is not likely to succeed. I am a firm believer that if a person tries hard enough and long enough, he will achieve whatever he reasonably sets out to do.—Banting, F. G.: Medical Research, *New York State J. Med.* 32:311 (March 15) 1932.

TREATMENT OF CARCINOMA OF THE CERVIX

THOMAS E. JONES, M.D.
CLEVELAND

On scanning the literature since 1900 on the treatment of cancer of the cervix one finds that three periods are represented. During the first period the surgical treatment was emphasized and the reports consisted chiefly of descriptions of operations and surgical end-results. Then there was the period of controversy concerning the relative merits of surgery and radium. During the past ten years in this country and with few exceptions on the continent, most of the literature has dealt with radiation therapy, its technic and the end-results. An analysis of these results would seem to indicate that, for the time being at least, radium and the roentgen rays are the treatment of choice, not only from the standpoint of the rate of curability, but also from the standpoint of palliation, morbidity and economy.

In this paper, I am reporting a series of 420 cases of cancer of the cervix, in which the patients were examined, treated and observed during the period from 1920 to 1931, inclusive. In this group there were 302 cases of primary carcinoma; in 80 there were recurrences following operation or irradiation elsewhere, and in 18 the lesions were too far advanced for any possible treatment. Twenty patients in this group refused treatment or sought medical advice elsewhere.

I shall not take time to discuss the diagnosis of carcinoma of the cervix. It has been dwelt on time after time. Yet on reviewing my series of cases, it is not pleasant to have to admit that in patients examined in 1931 the disease was just as far advanced as it was in those examined in 1920, in spite of numerous articles written on the subject and in spite of the publicity given it by The Society for the Control of Cancer. Despite the fact that the cervix is an easily accessible organ, failure to recognize early cervical cancer has occurred in a discouraging number of cases. Delinquency on the part of the patient is sometimes responsible, but with increasing public education this is becoming less frequent, and still entirely too many failures are attributable to the remissions of the medical profession.

Diagnostic failures come about in two ways: The symptoms may be attributed to the menopause, and frequently consultation without proper examination leaves the patient with a false sense of security which leads to further delay. The lesion may be discovered but may not be recognized as malignant, being mistaken for an ulcer, erosion or eversion. In case of doubt a biopsy is imperative. The physician's hesitancy to do a biopsy may have resulted from the active discussion a few years ago of the danger of spreading the cancer in this way. Today that discussion is dead—so are many patients for lack of a biopsy. I have never seen any harm come from it and recommend its use in any doubtful case. It will save far more patients than it will harm.

Another fallacious opinion has been advanced in an effort to show that irradiation by both the roentgen rays and radium may cause distant metastases not seen heretofore. The literature shows that many distant and

Read before the Section on Obstetrics, Gynecology and Abdominal Surgery at the Eighty-Third Annual Session of the American Medical Association, New Orleans, May 13, 1932.

bizarre metastases were observed long before radium was used. If metastases are being observed more frequently now, it is because radiation has prolonged the life of the patient for sufficient time to make this observation possible. On noting the cause of death in my series, it was found that practically all the patients died with the disease confined to the pelvis with obstruction to the ureter only. Very few showed metastases to the liver, lungs and bones.

Any one who has treated a large group of patients is at once impressed by the varied individual resistance to cancer. Some patients with apparently advanced lesions respond better than those in whom the disease is recognized early. This variation in response is undoubtedly attributable to normal body defenses about which little is known. However, Broders has developed a method of evaluation of malignancy histologically, by which the prognosis in a given case may be expressed on a numerical basis, the cases being divided into four groups according to the degree of cellular differentiation. Following these lines, a tremendous amount of investigation has been carried on by other workers for the purpose of determining whether there is any definite relationship between the histologic structure of carcinoma and its relative malignancy and of trying to deduce from this finding the best form of treatment for the type in question and also of determining the prognosis. I have not been able to test this out in my series of cases, because I believe that a large personal equation enters into the problem and that direct, personal contact with Broders would be necessary in order to develop a precise duplication of his method. If not done properly, I am sure that such an attempted classification would lead to further confusion. Another complication, of course, is that sections from different portions of the tumor may give different histologic pictures which also may be misleading.

The clinical classification I use is that of the American College of Surgeons, which, for working purposes, is quite practicable except in regard to the question of involvement of the broad ligaments. It is often difficult at first examination to decide whether or not such involvement may be inflammatory or malignant, but time generally furnishes this information. I believe that cures in cases in which there is definite infiltration of the broad ligament are relatively few.

RATIONALE AND TECHNIC OF RADIUM THERAPY

For practical purposes, the simple idea that radium is a means of destroying cancer cells without too much injury to the normal cells is a good working hypothesis, but accumulating knowledge of the physics of radiation and of the biologic effects of radiation is leading to better understanding of its action. In brief, radium has a threefold action on malignant tissue: It affects (1) the cancer cells, (2) the connective tissue and (3) the blood and lymph vessels. The action on the cancer cell is shown microscopically by swelling and vacuolization of the protoplasm and by shrinking of the nuclei. This is followed by phagocytosis and absorption and replacement by homogeneous connective tissue. This contracts and affects the lymphatic and smaller blood vessels and starves the growth.

There is not sufficient time to enumerate the varieties of technic that have been used since radium therapy was instituted nor to mention all of the men who have contributed to the advancement of the present knowledge. Suffice it to say that there are two entirely different schools of thought in regard to the method of treatment. In one, the opinion is that it is best to give large massive doses within a short space of time, preferably in one or, at the most, two treatments. The other is that it is preferable to give very small doses over a longer period of time. I believe that most of the large clinics in this country favor the former view, while protagonists of the latter method are led by Regaud of the Radium Institute of Paris. This difference of opinion undoubtedly will be settled before many years elapse, when the results of both methods may be compared. Standardization of the dosage of radium used in treating uterine cancer is impracticable; the dosage and technic must vary with the character and location of the lesion.

The technic followed in the Cleveland Clinic has varied but little during the last ten years, the only change being that since a larger amount of radium has been available, larger doses have been given over a shorter period of time, and an effort has been made to give the complete dose at one sitting. Previously, the total irradiation was given in two doses. The average dose given in the first cases in my series was 4,200 milligram hours distributed evenly in and against the cervix. In later cases, since radium has been combined with roentgen rays of high voltage, the average dose is about 3,600 milligram hours. The standard screen is made of brass, 1.5 mm. in thickness, and this is encased in a rubber tube 3 mm. thick. At the present time a tube is placed in the fundus as well as in the cervix. This is done because in some patients who were treated earlier it was found that after being free from symptoms for a year or so, the patient suddenly had bleeding and discharge, and examination would reveal a large undermined cavity at the upper end of the cervical canal which had not been reached by the radium. It is necessary to anesthetize the patient in order to determine the extent of the new growth and to place the radium accurately. However, it is sometimes impossible, even when the patient is under an anesthetic, to place a tube of radium high in the cervical canal.

In addition to the radium tubes placed in the fundus and cervix, two or three tubes are placed against the cervix, and these are held in place by packing the vagina tightly with gauze. If the growth is of the cauliflower type, it is frequently curretted away or implanted with radium needles. A catheter is placed in the bladder in order to keep it empty and as far away from the radium as possible. Care should be taken in transferring the patient from the table to the cart and from the cart to the bed. Bending and twisting of the patient during the transfer may dislocate the vaginal tube and may account for bladder and rectal symptoms. The best method is to place the cart alongside the table and to slide the patient on the cart by means of a sheet, and to transfer her from the cart to the bed in the same manner, so that the position is unchanged throughout the procedure. Gold seeds have not been used in the treatment of any of the patients, but they are of great value in cases in which there has been recurrence, because their action is localized to a greater or lesser extent. Large heavily filtered doses frequently are harmful in the treatment of lesions that have recurred. In this series there has been no case in which gold seeds were placed in the broad ligaments by laparotomy. From three to four weeks after treatment with radium the patient returns to the clinic for a course of treatments with high voltage roentgen rays, given in five or six doses during a period of five or six days.

After patients have been treated they are requested to return at monthly intervals for three months, and afterward every three months during the following year. If local recurrences develop, they are treated by means of implantation of seeds. If the recurrence is deep, roentgen therapy is repeated, with marked relief for a time. In cases of intractable pain in the pelvis and down the legs, cordotomy may be done. Section of the sensory column in the cord affords amazing relief from pain.

COMPLICATIONS

The chief complications in the treatment of carcinoma of the cervix by radium are hemorrhage, symptoms referable to the rectum and bladder and fistulas, both urinary and fecal.

Hemorrhage.—This may be due to the natural progress of the disease or to ulceration caused by the radium. I believe that the natural progress of the cancer is the principal cause of hemorrhage. In the most serious cases packing and transfusion are sufficient to control the hemorrhage.

Bladder and Rectal Symptoms.—These symptoms are of two types, early and late, and it is quite important that they should be recognized. It is reasonable to assume that if a sufficient dose of radium is given to cure carcinoma of the cervix, it will also be sufficient to produce an erythema in the rectum or bladder. Frequently this erythema is slight and passes unnoticed unless the patient is questioned. If it is severe, it is evidenced by a burning sensation and a tendency to frequency of urination or defecation. In mild cases, the condition usually clears up within ten days or two weeks, but in severe cases from four to six weeks may be required. It is in the latter group, in which the symptoms persist, that late rectal and bladder complications may develop, usually six or eight months after the initial irradiation. These late symptoms frequently are mistaken for a recurrence of the carcinoma, and if the patient is given additional treatment with radium, irreparable damage may result. A clue to the true state of affairs is found in the fact that the symptoms are out of all proportion to the findings. There are severe pain and tenesmus, and the stool contains considerable blood and mucus. Digital examination causes greater pain than in the case in which there is recurrence of the malignant lesion. The patient is not cachectic. Proctoscopic examination reveals, approximately at the level of the cervix, a puckered scar or small ulcer with telangiectasis and considerable redness of the mucosa. The condition may be compared to an overtreated area on the skin which is healed by the formation of scar tissue through which fine vessels may be seen to course. In the rectum the scarring is subject to trauma and infection with subsequent ulceration, which causes the late symptoms.

The same general condition is to be found in cases in which there are late bladder symptoms. Cystoscopic examination may reveal an area of intense redness and, at times, ulceration. I have observed several cases of this type over a period of months, and a few over a period of two years. Occasionally the urinary salts will be found deposited in the slough in the bladder, and stones will be formed. For the rectal symptoms the treatment consists of rest in bed, cleansing of the lower part of the bowel and the injection of 3 or 4 ounces (89 or 118 cc.) of warm olive oil into the rectum twice a day. Occasionally an opium suppository is necessary. For the bladder symptoms rest, irrigation of the bladder and the instillation of gomenol are prescribed. Sometimes these bladder and rectal complications may not disappear for from four to six months.

Fistulas.—It is known that the natural progression of carcinoma of the cervix will cause a certain number of fistulas into the rectum or the bladder. In some of my earlier cases fistulas may have resulted from treatment of the carcinoma, but with present knowledge and the improved methods of treatment, I feel sure that the incidence of fistula will be lower than in cases in which the patient has received no treatment at all. If the fistula appears soon after treatment, it is interpreted as being due to destruction from the disease. If it appears late and there is no evidence of recurrence of the carcinoma, it probably is due either to progressive ulceration or to the later complications mentioned, and hence is the direct result of the treatment with radium.

The method of treatment of a fistula in the rectum must depend on its size and the amount of inconvenience it causes the patient. A small fistula may not require treatment. If a large fistula is present, it may be advisable to do a colostomy before attempting to repair it and to close the colostomy if and when the repair is successful.

The urinary fistula is more annoying on account of the constant flow of urine. If the fistula is small, it can be repaired easily by operation. If it is irreparable, the patient may be made more comfortable by transplantation of the ureters into the sigmoid.

Of the total number of patients with primary carcinoma of the cervix coming to the clinic, some attempt at treatment has been made in 93 per cent. The remaining 7 per cent were moribund on admission. The accompanying table gives the statistics of the results of treatment in 303 cases of primary carcinoma of the cervix from 1920 to 1931, inclusive. All patients not traced are counted as dead. It will be seen that of 148 patients treated over five years ago, 37, or 25 per cent, are alive and well. Twenty-nine per cent are living after from three to five years, and 61 per cent are living under three years.

With increasing facilities throughout the country to take care of these patients, it seems to me that the biggest problem still remains, that of getting the patients to seek medical advice when the disease is still in an early stage.

ABSTRACT OF DISCUSSION

Dr. W. P. Healy, New York: In cancer of the cervix, early diagnosis is impossible except by accident. The majority of the cases of cancer of the cervix begin beneath the mucous membrane, are of the anatomically infiltrating type, and fail to give symptoms while they can be regarded as early cases. The only symptom the woman has which may lead her to suspect cancer is the appearance of blood as the result of contact, following intercourse or the use of a douche tube, or occurring between periods from ulceration. She cannot have bleeding without having destruction of tissue, and destruction of tissue must mean open lymphatics, through which cancer cells are readily disseminated beyond the primary focus. This is why early cases are not seen. Ninety-four per cent, approximately, of these cancers of the cervix develop in women who have borne children. I believe more attention should be given to prophylaxis in cancer of the cervix, probably much more than to treatment. A report from the clinic of Dr. Graves, at the Brookline Free Hospital for Women in Boston, indicated the great value of the use of the cautery in the treatment of nonmalignant cervical lesions. In approximately 2,500 of their cases so treated with the cautery for benign lesions of the cervix, over a period now of many years up to the present time, in no single instance has cancer appeared in any of those cervices subsequently. On the other hand, in cases of cervical disease which they regarded as suitable for plastic surgery, their pathologist reported cancer of the cervix as an accidental finding in some of the cases. If the same men, therefore, made an error of diagnosis in a case that they thought suitable for plastic surgery, it seems to me reasonable to assume that they must have used the cautery in treating cases of early cancer of the cervix through an error in diagnosis, and certainly they cured the patients, because in no single instance of the 2,500-odd cases has cancer appeared. Therefore, I believe it is the duty of physicians to follow cases of pregnancy more closely in their first six months post partum than is customary, because with the present-day methods of office treatment of cervical lesions with a cautery, the cervix can certainly be restored to a normal condition readily and easily.

Dr. Wallace Frank, Louisville, Ky.: From 1917 to 1927 I treated 180 cases of primary carcinoma of the cervix. A follow-up was conducted on those last October, and replies were received from about 100. It must naturally be assumed, therefore, that the other 80 patients are dead. Many of the cases were well advanced and were treated for palliation alone, to relieve the bleeding and to relieve discharge. Of the number of cures of patients who are alive from five to fourteen years after treatment, there are thirty-four, giving a percentage of cures of 18.9. Dr. Healy just remarked about the rarity of finding early cases. In my 180 cases there were but 15 early ones, and 12 of the patients are now alive; one lived eight years and died of apoplexy without any return of her disease, and two are dead, giving a proportion of cures in the early cases of 86.4 per cent. I might say that all these patients were treated by x-rays and radium or by radium alone. I am not operating on cancers of the cervix any longer. In but two cases did fistulas develop and those came on between eight and twelve months after treatment and consequently I was certain that they were due to the natural progress of the disease rather than to irradiation. It has been my observation that cancer of the cervix is being seen in younger women, and a larger percentage of cases in the past five years has occurred between the ages of 30 to 40. It is important, therefore, to suspect malignancy at this period of life and carefully examine the patients so that early growths will not be overlooked.

Dr. James E. Davis, Detroit: With regard to the early diagnosis of cancer of the cervix, it probably would be of great advantage if physicians were obliged to take about thirty or thirty-five minutes to examine a cervix suspected of carcinoma. Further, I think the safety of the patient would be advanced about 15 per cent if cancer structurally grew with a number of thorns around the peripheral surface. I say that because then the cancer would be handled gently. In the practical examination of the cervix I believe great aid can be secured if one will divide the cervix into two planes (I am speaking now of the cervix in the early stage of cancer growth): one plane to include that part of the cervix which one is reasonably sure is not involved in the cancer process, and the other plane to include the parts suspected. One's examination might begin with a careful survey of the surface that is covered by the stratified epithelium, and if one has not tried this practice of examining critically and slowly the stratified epithelial surface, one will be surprised how much one will learn by taking adequate time and using one's eyes critically in the examination. Secondly, one might aid the ocular examination by using some simple tissue stain and observing the deeper intensity of the stain in the carcinomatous tissue if there is any present. Further, the division of carcinoma into two groups only would simplify our understanding. One might be called the adenocarcinoma, which is the smaller group, perhaps not making up a higher percentage than 6; the other group is the epidermoid type of carcinoma. That would simplify many of the problems of the pathologist and I think some of the problems of the clinician. In regard to the obtaining of biopsy material, if a sharp knife is used and one keeps on cautioning oneself about avoiding unnecessary manipulation of the cervix, one can take a biopsy section, I am quite sure, without scarcely any danger to the patient. The manipulation of the cervix is an exceedingly dangerous procedure.

ENDEMIC EDEMA

JOHN B. YOUMANS, M.D.
NASHVILLE, TENN.

Nutritional edema may occur in epidemics in populations whose diet is inadequate for a time, as happened in the Central Powers during the World War.[1] It may exist in endemic form in populations whose diet is always more or less inadequate, as in China.[2] It also appears sporadically, most often because of some disease which interferes with the proper intake or absorption and utilization of food.[3] Since the World War it has been shown conclusively that the disease is associated with a hypoproteinemia, presumably due to an insufficient intake or utilization of protein.[4] A similar edema, with an accompanying hypoproteinemia, has been reproduced experimentally in animals by feeding a diet low in protein.[5] Recently other studies have emphasized the important relationship between the plasma proteins and certain forms of edema.[6]

In this country studies of nutritional edema have dealt with sporadic cases, and the existence of endemic nutritional edema has scarcely been suspected. For several years, however, cases of edema have been observed at the Vanderbilt University Hospital which are apparently nutritional in origin.[7] Except for incidental and unrelated conditions, they are not accompanied by other disease. Most of the cases have occurred

in the spring and early summer. In late summer new cases fail to appear and the others tend to lose their edema. Occasional cases are seen during the fall and winter. The edema is from slight to moderate in the majority, involving the feet and legs most often, but sometimes the face and hands as well. Some of the patients have complained of mild pain and tenderness in the extremities. Most of the patients are women and all ages are included. The duration of the edema has varied from a few days to years, the edema occurring intermittently in the latter group. Only about one half of the patients have been underweight and a few have been obese. In nearly all, however, a loss of weight preceded the onset of edema. The absence of other causes and the number of cases suggested that this edema was nutritional in origin although there was no unusual cause for undernutrition and at the time the first cases were detected the economic situation was generally satisfactory. It was known, however, that the customary diet of a large part of the population in this part of Tennessee was such that the protein content might be low. Preliminary studies showed the total serum protein to be normal or higher than normal. Later, studies of the protein fractions showed that though the total was usually normal there was a slight to moderate reduction in the serum albumin, the normal total being due to a high normal, or abnormally high, globulin. So far, more than fifty of these cases have been observed and a number have been studied in some detail. The investigation has included, among other things, an investigation of the diet, determinations of the serum proteins and studies of nitrogen balance. A number of the patients have been followed over periods of weeks to years and the course of the disease under various conditions has been observed. All but two of the patients have been studied exclusively in the outpatient department.

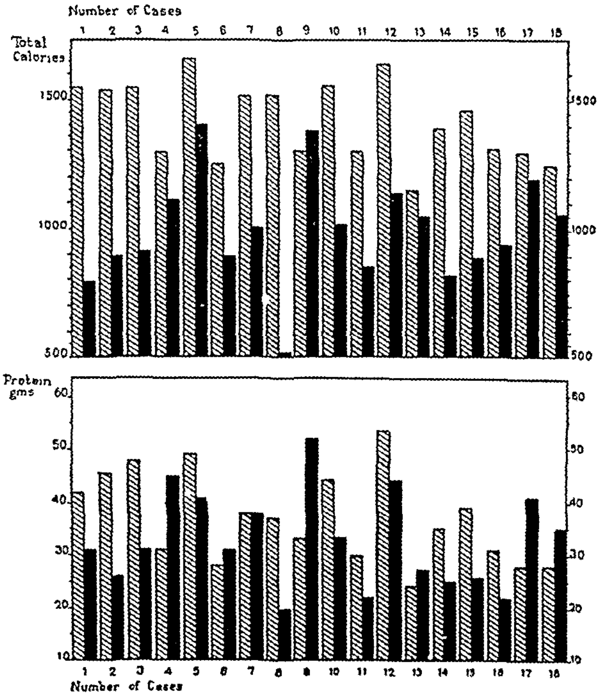

Chart 1.—The average total calory and protein intake per day of eighteen patients with nutritional edema. In each instance the calculated basal caloric requirement and minimal protein requirement (0.6 Gm. per kilogram) are presented for comparison. The solid columns represent the actual intake and the shaded columns the calculated requirements, each pair of columns representing a single case.

DIET

A study of the diet was made by having the patient keep an accurate record of the food eaten for a number of days. Printed slips were provided on which the amounts and kind of food taken each day were recorded and from which the average daily intake of protein, animal protein, carbohydrate, fat and total calories was calculated. The procedure was carefully explained to the patient, not only by the physician but by a social worker who sometimes visited the patient at home to assist in keeping the record and check its accuracy. Part of the data from eighteen cases are shown graphically in chart 1. In every instance but one the caloric value of the diet was below the calculated basal requirements. Since all were outpatients and more or less active, the actual deficiency was much greater. The average daily intake of protein was low, ranging from 20 to 52 Gm. daily and in twelve was at or below the usually accepted minimum (0.6 Gm. per kilogram). In the others it was below 1 Gm. per kilogram. Although the records are believed to be fairly accurate, the total number of calories was probably somewhat greater than is recorded. Considerable amounts of fat were used in cooking, and have not been taken into account. The daily records showed considerable variation, and had the study been made over a longer period it is probable that a higher average would have been found. The study was made when the edema was present, and the diet may have been unusually poor at that time. No allowance has been made for the availability and character of the protein or for the possible loss of protein in the stool, which may have been

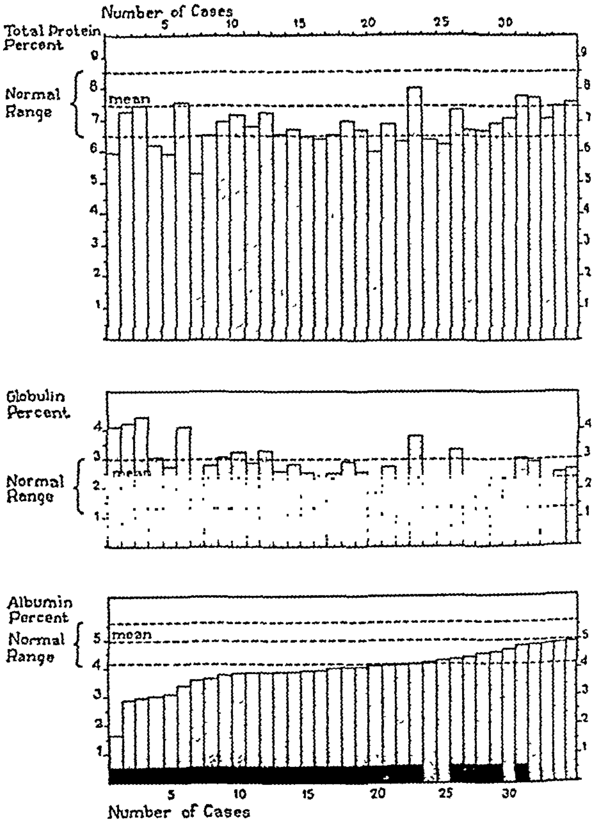

Chart 2.—The initial determination of the serum proteins in thirty-five cases of nutritional edema, arranged in ascending order of the values for serum albumin. Each column represents an individual case. The shading in the bottom columns indicates the presence of edema. In the nonedematous subjects edema had been present before the serum proteins were determined.

greater than usual. It must also be remembered that a minimum protein intake is sufficient only when the calories are abundant. In general, it appears that the diet of this group was characterized by a caloric intake which was always near, and frequently dipped below, the bare maintenance level and by a minimum amount or less of protein. It is probable that the deficiency had existed for a long time in most instances, perhaps for a greater part of the patients' lives. There is reason to believe also that the character of the diet was not due solely to economic causes, but was partly the result of custom and habit.

SERUM PROTEINS

The initial serum protein values[8] in thirty-five cases are shown in chart 2. In most instances the total protein is within the normal range. Values below the lower limit of normal are found in only nine, but in twenty-three the total protein is below the average normal. The albumin protein shows more significant changes. The individual values range from 1.72 to 4.97 per cent, with an average of 4.00 per cent, which is distinctly below the normal lower limit. More significantly, the individual values are at or below the lower limit of normal in twenty-two of the thirty-five. In contrast to the albumin, the globulin is above the normal average in all but eight cases, and in eleven is above the upper limit of normal. The globulin is not below the lower limit of normal in a single case. Thus, the high globulin accounts for the normal total protein. The inclusion of cases without edema is explained by the fact that in some instances the examinations were not made until after the edema had disappeared. The presence of edema with a normal albumin may be due in part to a lag in the disappearance of the edema, and in most of these instances the edema was absent a short time later.

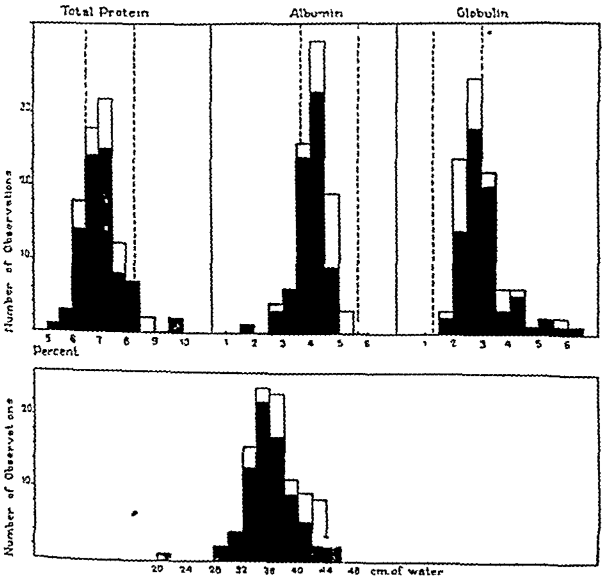

Chart 3.—The relation of the serum proteins and of the calculated colloid osmotic pressures of the serum to the edema. The osmotic pressures have been calculated by the use of Govaerts' factors (Bull. Acad. roy. de méd. de Belgique 7: 356, 1927). The black areas indicate the presence of edema. The broken lines indicate the "normal" range.

In the patients who were followed a sufficient length of time the edema tended to disappear when the protein in the diet was increased and as the serum albumin rose. This relationship was obscured, however, by the lag in the disappearance of the edema, the inability to control accurately the diet and activities of the patients and the irregular intervals between observations. Furthermore, there were spontaneous fluctuations in the edema which could not be related to any known cause. It is interesting that a considerable period of time was necessary before the serum proteins returned to normal. This was not due entirely to a failure to take the diet recommended, as shown by the fact that one of the patients was treated in the hospital with a high protein diet for ten days with little effect on the serum albumin, which did not reach its maximum until some weeks after the patient was discharged, though the same diet was continued. It is possible, since the albumin continued to rise, that nitrogen retention persisted during this period, though neither the present studies nor those of others had been continued sufficiently long to demonstrate this. The observations suggest that in nutritional edema the depleted nitrogen stores of the body are replenished before the blood proteins are greatly increased or that some difficulty exists in the absorption or utilization of protein.

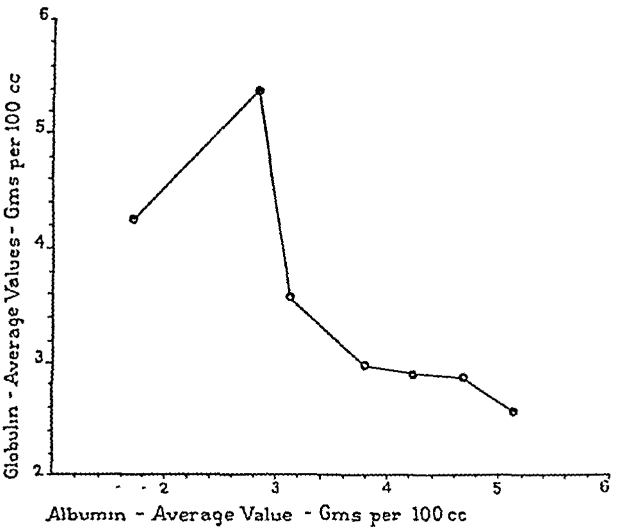

Chart 4.—In this figure the average values for each group of albumin determinations at 0.5 per cent intervals (1.50-1.99, 2.00-2.49, etc.) have been determined and the average values for the corresponding globulin determinations plotted against them. The first point represents a single determination only. The tendency for the globulin to fall as the albumin values rise is evident.

In attempting to correlate the changes in the serum protein with the presence or absence of the edema the data obtained by repeated examinations of some of the patients were combined with the results of the initial determinations. One hundred determinations were available for this purpose (chart 3). No correlation was found between the total protein, which was usually normal, and the presence or degree of edema. There was some apparent relation between the lowered albumin and the presence of edema, but for reasons to be discussed it is not very close. There was a tendency toward an opposite relationship in the case of globulin, and high values for globulin were often found associated with edema. It is interesting to compare these observations with the correlation between edema and the total colloid osmotic pressure. Since albumin has an osmotic pressure approximately four times that of globulin, it is to be expected that a decrease in the former would cause a significant drop in colloid osmotic pressure in spite of a normal or increased globulin. Correlation is not greatly improved, however, probably because of the same factors that are active in the case of the albumin.

---

[8] The serum proteins were determined by the use of Howe's method for fractioning the proteins (J. Biol. Chem. 49: 93, 1921) and the macro Kjeldahl procedure. A more complete description will be published later. The standards of normal that were adopted are: average values, total protein 7.30 per cent, albumin, 5 per cent, and globulin, 2.3 per cent; normal range, total protein from 6.5 to 8.5 per cent, albumin from 4.2 to 5.7 per cent and globulin from 1.3 to 3.0 per cent.

An increase in the serum globulin occurred too often and was too great to be considered merely coincidental. Neither is there any evidence that the high globulin was the result of such factors as infection. It was observed that as the albumin fell the globulin tended to rise and vice versa. This relation between the globulin and albumin is shown in chart 4. I believe that it represents a compensatory reaction, which is usually incomplete and insufficient to prevent the formation of edema.

Studies of the nitrogen metabolism in two patients showed a slightly negative nitrogen balance when they were placed in bed and given the same diet that they were taking when the edema developed. Increasing the nitrogen intake resulted in a slight to moderate retention of nitrogen, which was not, however, associated with a prompt increase in serum albumin. However, in one case which was followed over a sufficient period the albumin gradually rose to normal and the edema disappeared.

COMMENT

These cases of edema differ in several respects from cases of nutritional edema reported by others, particularly those seen during epidemics. In general, the disease is milder and the patients are less severely undernourished. The symptoms of severe undernutrition, bradycardia, hypotension, subnormal temperature, lowered metabolic rate, etc., are lacking. The absence of any disease causing the malnutrition distinguishes them from most of the sporadic cases. The changes in the serum protein are consistent with the mild nature of the symptoms. Greater reductions in the serum proteins have been reported by other writers. In some instances variations in the methods are responsible for the difference. Much more important is the difference in the severity of the disease and the circumstances under which the present studies were made. A lowered osmotic pressure due to lessened serum proteins is but one of the two principal factors at present thought to be concerned in this form of edema and determines *only a tendency* to edema. The other factor is capillary pressure, and the occurrence of edema probably depends primarily on the balance of force between the capillary pressure tending to push fluid out of the vessels and the osmotic pressure tending to hold it in. An increase in capillary pressure can cause a filtration of water from the blood in the presence of normal amounts of protein. Krogh, Landis and Turner[9] have recently shown that the erect human being is always near edema. Therefore, even a slight reduction in serum protein might result in the formation of edema, provided the capillary pressure remained unchanged, and edema would be more apt to occur if the capillary pressure were increased. All the patients studied were ambulatory patients, more or less engaged in their usual activities, and it might be expected, therefore, that edema would occur at higher concentrations of serum protein than in patients who were confined to the hospital and whose activities were greatly restricted. The influence of the restriction of physical activity is well shown by the two patients who were hospitalized and who quickly lost 4 and 2 Kg., respectively, with little or no change in the diet.

The lack of closer correspondence between the changes in the serum albumin and the occurrence of edema is possibly the result of several factors, among which are the influence of physical activity, the lag in the appearance or disappearance of the edema, uncontrolled variations in salt and water intake, the intermittent and chronic nature of the disease, variations in the serum globulin and the irregularity and infrequency of the observations in the cases in which repeated observations were made. Nevertheless it is possible that other factors, as yet unknown, may be concerned with the development of edema in these patients.

These cases have an importance out of all proportion to the mildness of the symptoms. They represent, I believe, the effect of a dietary inadequacy of slight degree but long duration. In the past, interest has been focused on relatively acute and well developed cases of deficiency disease in which there exist gross inadequacies. At present attention is being directed to milder and more chronic disorders, to the effect of minimum or suboptimum conditions of diet, rather than severe deficiencies. Disease which is the result of gross inadequacy may be of greater individual importance, but, on the other hand, is more easily and earlier detected and remedied. Less serious errors in diet, with their greater frequency and more subtle effect on a population, are of vastly greater general importance. In the present cases the edema itself probably has little harmful effect on the patient. If, as seems likely, the principal dietary inadequacy in these cases is a lack of protein, the edema is important only so far as it indicates a prolonged but mild protein insufficiency. Relatively little is known regarding the effect of such a deprivation in man or what constitutes the optimum amount of this food substance. Certain older studies, such as those of Chittenden,[10] have indicated that bodily health and vigor are not only maintained but even improved on an amount of protein much lower than is ordinarily considered necessary. More recent studies have challenged this belief. McCollum,[11] who favors a higher protein intake, has pointed out, for example, that the nine months' period of Chittenden's experiments represents but 1 per cent of man's normal life span, a period too short to warrant far-reaching and final conclusions. It is true that in man no clearcut symptoms or syndrome results from a long-continued minimal intake of protein. On the basis of animal experiments and general clinical observation it has been suggested that a minimum amount of protein results in diminished resistance to disease, lessened fertility, early senility, anemia and a significant decrease in mental and bodily efficiency and stamina. The present study has not included an investigation of the occurrence of such disorders among the subjects. Neither can great significance be attached to general clinical observations. Nevertheless it seems fair to state that experience among the population from which these patients are drawn has indicated a high incidence of many of the conditions listed. One is also led to the consideration of a possible relation between the dietary insufficiency and certain social and economic characteristics of the same population. For the present, however, these observations are, at most, only suggestive. It is realized that the diets that have been recorded may be inadequate in other respects than protein. They are known to be at least close to the bare maintenance level in total calories. Pellagra occurs among this same group of patients. In spite of a considerable intake of leafy vegetables there is reason to believe that this diet may be lacking in the important vitamin B. Many of the disease conditions which might be ascribed to a lack of protein are also attributed to a lack of other specific food substances. It is difficult under clinical conditions to study the results of an inadequacy of single food constituents; multiple deficiencies nearly always exist. It is likewise difficult to understand why with closely similar diets some patients will develop pellagra, others anemia and still others a nutritional edema. Yet the occurrence of such an edema, with changes in the serum proteins in persons whose diets contain a minimum of protein or less cannot but suggest the importance of protein in the diet and a possible relation between a deficiency of protein and other abnormal conditions encountered in these patients.

SUMMARY

Cases of edema, apparently nutritional in origin and endemic in nature, have been observed in this clinic. The usual diets of the patients have been found to be low or minimal in total calories and in proteins. Studies of the serum proteins have shown the total protein usually within the limits of normal, the serum albumin slightly to moderately reduced and the globulin normal or increased. The edema has shown an irregular tendency to disappear as the protein intake is increased and as the serum albumin rises. The significance of these observations is discussed

ABSTRACT OF DISCUSSION

Dr. Roy H. Turner, New Orleans: There is a great contrast between the presence of slight edema in Dr. Youmans' cases, with an almost normal serum protein concentration, as compared with some of the patients one sees with pellagra who have an extreme diminution in serum proteins and also have little or no edema. The tendency to edema in pellagra usually is extremely slight, whereas the tendency to edema in spite of almost normal serum proteins is marked in the patients described by Dr. Youmans. It is easy to guess at some of the causes, but one can't be sure of the explanation. Certainly, pellagrins lying in bed, and they tend to lie quietly indeed, do not have the high capillary pressure, very likely, that exists in the dependent portions of the erect body. They also suffer from diarrhea, which offers a ready means for the escape of fluids and salts from the body. The two groups certainly illustrate the necessity for common sense explanation coupled with accurate observation in the interpretation of laboratory data. It is fascinating to speculate whether beriberi in a mild form plays a part in this condition. Dr. Youmans intimated that it might, but I should like to have him make a more definite statement in that direction. It seems that it is not yet known why edema is present in the wet form of beriberi. When attention was recently centered on lower protein concentration of blood serum, many people assumed that this was the cause of the edema in wet beriberi. So far no one has reported the proper observations; recently, however, I have had personal communication that such observations have been made in China, and there is not a diminution in the concentration of protein there. Whether there is another vitamin having to do with edema that is independent of the antineuritic factor is not generally believed, and yet there are those who do not believe that heart failure is the cause. I think Dr. Youmans has stated that antineuritic vitamin has not been effective in these cases. I should like to know more definitely about that.

Dr. John B. Youmans, Nashville, Tenn.: A number of these patients were digitalized on the supposition that they were cases of mild cardiac failure, but most of them continued to get more edematous. I should like to emphasize that additional factors are involved in the edema. The principal factors concerned are supposed to be the lowering of the serum proteins and the capillary pressure, one balanced against the other, but salt and water intake, for example, are extremely important. A patient is now being treated whose edema can be increased or decreased at will by giving or withholding salt and water. I know of no final means of proving that these are not cases of mild beriberi. The only thing to suggest beriberi has been the edema, and the slight pain and tenderness in the extremities. It is curious that among so many mild cases there should be no clear-cut cases of beriberi, if this condition is beriberi. None of the patients have shown definite peripheral nerve changes. I have tried vitamin B in the form of brewers' yeast and have not been able to satisfy myself as yet that it has any definite effect on the disease.

ULTIMATE RESULTS FROM OPERATIONS ON THE BILIARY TRACT

E. STARR JUDD, M.D.
AND
JAMES T. PRIESTLEY, M.D.
Fellow in Surgery, the Mayo Foundation
ROCHESTER, MINN.

The true criterion for judging the merit of various types of operations for benign lesions, aside from consideration of immediate operative risk, resides in an accurate appreciation of the ultimate benefit to the patient. Unfortunately a true evaluation of end-results over a long period of time is always difficult; questionnaires are frequently unsatisfactory and personal interviews often impossible. The data presented here were culled from replies to a questionnaire sent to all patients operated on at the Mayo Clinic for benign disease of the biliary tract in the years from 1907 to 1910, inclusive. Many of the letters were discarded because they were vague or indefinite, and the information could not be accurately classified. An effort was made to arrange the available material in a manner suitable for judging ultimate prognosis and evaluating current operative procedures.

From 1,652 questionnaires, 606 satisfactory replies were received, either from the home physician or, in most instances, from the patients themselves. Sixty-four of the patients had died recently, but full information concerning their condition was obtainable. Of the entire group of 1,652 patients, 312 are known to be dead. From the point of view of diagnosis, complete data were obtained concerning 534 patients with cholelithiasis and 72 patients with cholecystitis without stones. From a surgical point of view, information was obtained concerning 426 patients following cholecystostomy, 121, following cholecystectomy and 59 subsequent to some type of operation on the common bile duct. An additional group of 53 patients originally operated on at the clinic between 1907 and 1910 and who returned to the clinic for further operation of the biliary tract will be considered separately, since late follow-up data were not obtained concerning all of them. However, the nature of the secondary operation and lesions encountered supplements our information concerning the first group, some of whom had subsequent operations performed elsewhere.

Read before the Section on Surgery, General and Abdominal, at the Eighty-Third Annual Session of the American Medical Association, New Orleans, May 12, 1932.

During the twenty-two years or more that have elapsed since these patients were operated on, the trend of surgery has kept abreast with growing knowledge of the physiology of the liver and biliary tract with the result that operative procedures have been somewhat altered and improved. The ultimate physiochemical basis for the cellular functions of the liver and its associated system of ducts both in health and in disease remains an enigma that must be solved before a thorough understanding and true appreciation of hepatic and biliary disease can exist. When this information is available, present-day surgical procedures may be greatly altered.

PREOPERATIVE DATA

During the earlier years only a relatively few patients (13.3 per cent) were subjected to operations on the biliary tract unless gallstones were present. It is now realized that in many cases the patient derives considerable benefit from removal of an infected gallbladder or drainage of the common bile duct for the treatment of cholangeitis whether or not stones are present at the time of operation. Many diseases of the gallbladder are now recognized sufficiently early to permit surgical treatment prior to the inevitable formation of calculi. As has been shown repeatedly, most patients with cholecystic disease are women; 80 per cent of those with cholelithiasis and 70 per cent of those with cholecystitis without stones were women. The difference is possibly accounted for by the cases of metabolic cholecystitis in which stone is so prone to form, and which are far more common among women than among men. The proportion of unmarried women is equally small in both groups (5 per cent). The average age for all patients was 42 years. The symptoms were much the same as are now observed, with the possible exception that they were usually more marked before surgical treatment was instituted.

Table 1.—*Cholecystitis with Cholelithiasis, Results More Than Twenty Years After Operation (534 Cases)*

Operation	Cases	Per Cent		
		Satisfactory	Unsatisfactory	Reoperation
Cholecystostomy..	376	58.6	24.4	17.0
Cholecystectomy	100	83.0	17.0	0
Choledochostomy and cholecystostomy	43	76.8	16.3	6.9
Choledochostomy with or without cholecystectomy.	15	86.6	13.4	0

Table 2.—*Cholecystitis Without Cholelithiasis, Results More Than Twenty Years After Operation (72 Cases)*

Operation	Cases	Per Cent		
		Satisfactory	Unsatisfactory	Reoperation
Cholecystostomy..	50	62.0	26.0	12.0
Cholecystectomy..	21	85.7	14.3	0
Cholecystostomy and choledochostomy	1	100.0	0	0

GENERAL RESULTS

Recurrence.—In general, cholecystectomy afforded results distinctly superior to those afforded by cholecystostomy. This was equally true regardless of the presence or absence of stones. Tables 1 and 2 illustrate the number of cases and the general results for the entire series of cases of cholelithiasis and of cholecystitis without stones. Good results were obtained following cholecystostomy in 60 per cent of cases, and following cholecystectomy in about 84 per cent. In none of these cases was a secondary operation required. A few patients had a recurrence of colic after the gallbladder had been removed. This was suggestive of disease of the gallbladder, but in no case was the condition sufficient to warrant operative treatment. During recent years we have encountered a definite group of cases in which, after a variable length of time following cholecystectomy, there is a typical clinical picture of stone in the common bile duct, except that jaundice is slight or more commonly absent. At exploration stones are not discovered and the underlying pathologic change appears obscure; however, symptomatic relief is complete following prolonged drainage of the common bile duct with a T-tube.

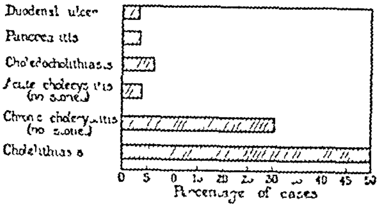

Chart 1.—The type of lesion encountered in fifty three cases in which a secondary operation was required following an initial cholecystostomy. A preponderance of cases of cholelithiasis may be noted

After an initial cholecystostomy for stones, there was a very definite group of cases (17 per cent) in which a recurrence of the trouble necessitated another operation on the gallbladder. The group in which symptomatic relief was incomplete was larger in cases in which the gallbladder was drained than in those in which it was removed. If the common bile duct is opened, in addition to some type of operation on the gallbladder, the percentage of satisfactory results seems to depend largely on whether the gallbladder is drained or removed. There is a greater possibility of later recurrence of stones in the common bile duct if cholecystostomy rather than cholecystectomy is performed at the original operation. This is in accord with the hypothesis that the majority of gallstones unquestionably develop within the gallbladder with the exception of the stones of pure pigment or calcium bilirubinate, which apparently form in the ducts themselves. Relatively speaking, this is an uncommon type of stone, and if all calculi are removed from the common bile and hepatic ducts at the first operation and cholecystectomy is performed at the same time, recurrence of stones in the common bile duct is extremely rare. Recurrent choledocholithiasis was not encountered in any of these cases following choledochostomy and cholecystectomy. Following choledochostomy and cholecystostomy there was recurrence in 6.9 per cent of cases which necessitated further operation because of the condition of the gallbladder or common bile duct. It seems reasonable to assume that the presence of a diseased gallbladder would predispose to the occurrence

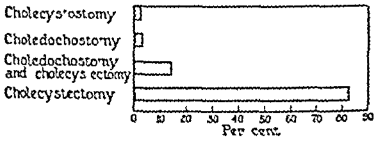

Chart 2.—Type of operation performed in the fifty-three cases in which a secondary operation was required following initial cholecystostomy

of choledocholithiasis since it is in this portion of the biliary system that most gallstones originate. In contrast, if cholecystectomy is performed initially, a potential focus for the formation of calculus is at once eliminated. One could hardly say that inadequate drainage of the common bile duct is responsible for the recurrence when cholecystostomy has been performed, as similar trouble did not develop if the gallbladder was removed at the initial operation when the common bile duct was opened.

Pathology.—The pathologic changes in cases in which recurrence following cholecystostomy definitely occurred varied, but for the most part were characterized by reformation of calculi in the gallbladder; this occurred in about 50 per cent of such cases. In a somewhat smaller group cholecystitis, chronic or acute, existed unassociated with stones. Less frequently choledocholithiasis, pancreatitis and duodenal ulcer were observed. As we have stated, when cholecystectomy was performed reoperation was not required in this series of cases. If a diseased gallbladder is merely drained and not removed, a potent focus of infection is permitted to remain. Chart 1 illustrates the relative frequency of the various types of lesions found in cases in which a secondary operation at the Mayo Clinic followed the original cholecystostomy between 1907 and 1910. The predominant lesion in these cases was cholelithiasis, and cholecystectomy was performed subsequently in most cases (83 per cent) (chart 2). In a smaller group it was necessary to perform choledochostomy, either with or without some operation on the gallbladder.

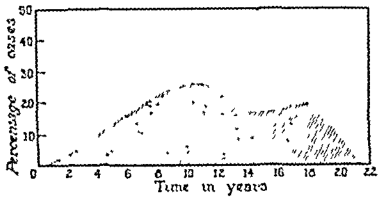

Chart 3.—The interval elapsing between the initial cholecystostomy and the secondary operation in 100 cases in which a recurrence of symptoms necessitated a second operation.

In 7 cases of choledocholithiasis requiring subsequent surgical treatment there was none in which cholecystectomy accompanied the original operation on the common bile duct. Only 4 of the patients required secondary choledochotomy; the remaining 3 were subjected to operation because of cholecystic disease unassociated with a lesion of the ducts. Had the gallbladder been removed primarily in these 7 cases, the possibility of permanent relief would have been greatly enhanced. In some cases, however, primary cholecystectomy performed at the time of choledochostomy is inadvisable. This may be true either because of jaundice in the presence of which one hesitates to remove the gallbladder and leave an oozing hepatic surface, or because of the possibility of utilizing the gallbladder in the future in maintaining free drainage of bile into the intestinal tract.

The interval elapsing between the first and second operations in the cases in which there was a recurrence varied considerably. Although frequently symptoms that later demanded surgical attention appeared within a few years after the initial operation, they were often absent much longer, a decade or more in some cases. Chart 3 illustrates the length of time between the two operations in a group of 100 cases of recurrence. The interim in about half our cases was more than ten years, which emphasizes the importance of a long period of observation if true end-results are to be ascertained. This, of course, does not mean that the recurrence of symptoms was necessarily delayed for so long an interval. At times this is of significance in observing the effects of an operation for choledocholithiasis. If jaundice or pain or chills and fever recur immediately following operation, it is probable that all the stones were not removed, whereas if there is a temporary relief of trouble and then recurrence, stricture of the common bile duct is more likely. Likewise, following cholecystectomy, if jaundice develops soon, one thinks first of an injury to the common bile duct at the time when the gallbladder was removed, whereas if there is a longer period of good health before further symptoms develop, choledocholithiasis becomes more probable.

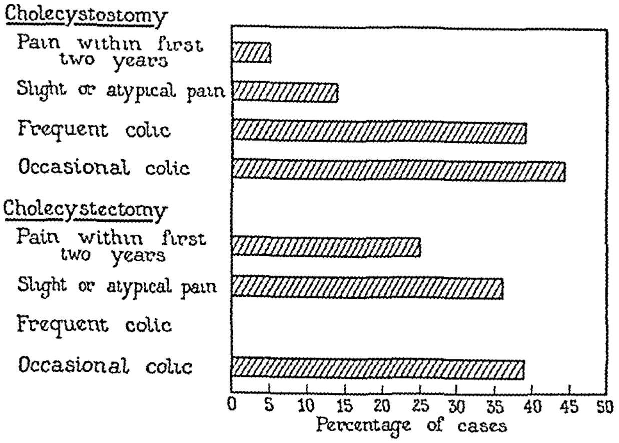

Chart 4.—Type of pain after cholecystostomy and after cholecystectomy. Thirty-nine per cent of the patients had some abdominal pain following cholecystostomy, whereas only 17 per cent experienced discomfort after cholecystectomy.

Postoperative Pain.—A definite number of patients experience pain in the upper part of the abdomen following an operation on the gallbladder, but this is not always indicative of further trouble in the biliary tract. In our cases it was far more common and more often related to the biliary tract following cholecystostomy than following cholecystectomy. Following drainage of the gallbladder, 38.1 per cent of the patients had some pain. If the gallbladder was removed, only 17.3 per cent complained of further pain. Subsequent to surgical drainage of the gallbladder 80 per cent of the patients experiencing pain had what was considered to

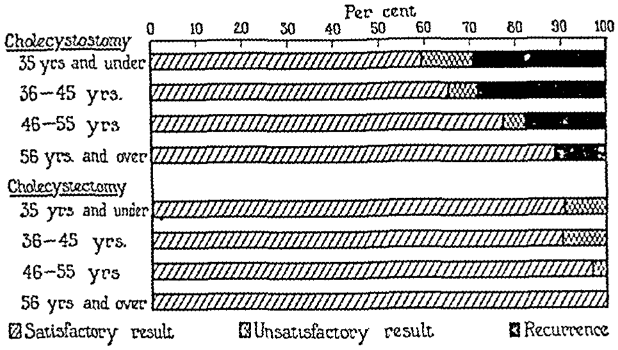

Chart 5.—The relationship between the age of the patient at the time of operation and the result obtained following cholecystostomy and cholecystectomy. A higher percentage of good results is reported by the older patients.

be typical gallbladder colic. A number of them had pain only infrequently, and with proper medical care at home avoided further operative procedures. The remainder had severe colic frequently, and constitutes the group, for the most part, for whom additional operation became necessary. The 20 per cent of patients who had some postoperative pain but not typical colic constituted a group whose pain did not seem directly referable to the biliary tract, except in a few instances in which it occurred soon after operation and then subsided completely. Following cholecystectomy (chart 4) only 17 per cent of the patients had any pain in the upper part of the abdomen, and this was usually not accounted for by recurrent biliary lesions. Only a third of this number had any typical colic. None had frequent severe colic. Pain within the first two years was relatively more common than following cholecystostomy, which might possibly be accounted for by the dilatation of the ducts known to occur following removal of the gallbladder. Comparatively more patients had slight or atypical pain following cholecystectomy. These results are what might be expected, as when the disease focus is completely removed, recurrence is far less common, and the point of origin for initiation of painful sensations is absent, for the most part, whereas following drainage alone there is a constant possibility of further trouble.

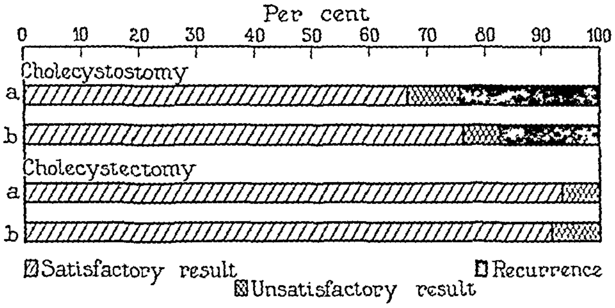

Chart 6.—The relationship between the preoperative symptoms and the end-result following cholecystostomy and cholecystectomy. The line *a* indicates symptomless or dyspepsia; the line *b*, colic, jaundice, chills, fever or some combination.

Factors Influencing Results.—Age seems to be a factor in influencing the results. A higher percentage of older patients experienced good ultimate results than the younger patients (chart 5). This was true following cholecystectomy as well as cholecystostomy. If it is considered that older patients probably have had the disease longer, and consequently advanced secondary changes in the bile ducts and the liver are more likely to have occurred, these observations would appear difficult to explain. There are probably other factors at work, and it does not seem necessary to conclude that the duration of the disease is proportionate with the age of the patient. Whether the appendix was removed at the original operation made no difference in the end-result. From this point of view the appendix cannot be considered a focus for disease of the upper part of the digestive and biliary tracts, although this relationship has been mentioned often. This does not mean that it may not be advisable to remove the appendix in operating on the gallbladder, but it should be removed only with the thought of preventing future local trouble. The preoperative symptoms are not so significant in the final result as one might expect, provided, of course, the original clinical diagnosis is correct. *Patients with colic, jaundice and chills and fever*, or some combination of these complaints, prior to cholecystostomy are likely to obtain more complete symptomatic relief than patients who complain chiefly of dyspepsia. The difference is not great, however, and after cholecystectomy it is even slightly reversed (chart 6).

The presence or absence of stones at the original operation is of some prognostic significance, as patients without stones had less subsequent trouble than those with stones, particularly if cholecystostomy had been performed. If the gallbladder is removed, the results seem to bear practically no relationship to the existence or nonexistence of stones. The general condition of the patient, the extent and nature of the lesion encountered and the type of operation performed are of primary importance in evaluating the prognosis following *operation on the biliary tract*. Other factors may appear to play some part in the ultimate result, but they are mainly of secondary significance.

PRESENT STATE OF HEALTH OR CAUSES OF DEATH

In recent years considerable attention has been given to the gallbladder as a focus of infection. This has been emphasized to such a degree that not infrequently cholecystectomy is now performed with the sole purpose of favorably influencing healing of lesions elsewhere in the body. The gallbladder has been most often condemned as a perpetrator of chronic infectious arthritis. Some observers have noted a supposed relationship between cholecystic disease and cardiovascular disease. In the group of 385 patients who are still living, *more than twenty years following operation on* the biliary tract, hypertension, arthritis, cardiac disease and apoplexy in the order named were found to be the most common causes of ill health at the present time. The frequency of these complaints was far in excess of the general incidence of these maladies, as quoted by actuarial statistics. They were usually more common among patients who had cholecystostomy rather than cholecystectomy. Furthermore, there were more than twice as many (27 per cent as compared with 11 per cent) who now complain of poor health following cholecystostomy than following cholecystectomy (chart 7). The relation between disease of the gallbladder or biliary tract and diseases of the joints or cardiovascular system seems quite definite.

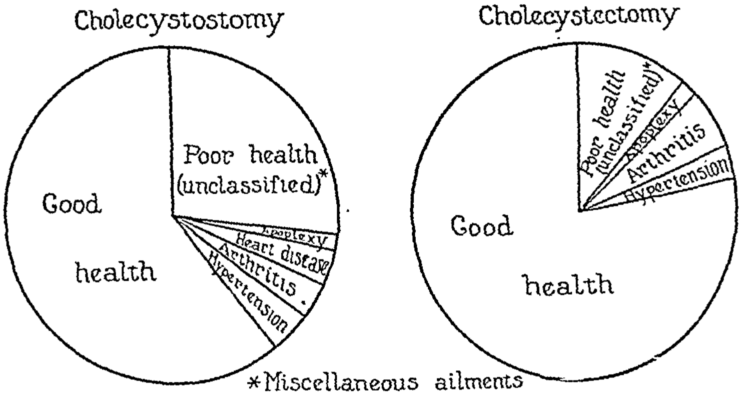

Chart 7.—The present state of health of 385 patients following cholecystostomy and following cholecystectomy. A much larger number of patients are in good health after removal of the gallbladder.

An analysis of the causes of death in 65 cases, in most of which cholecystostomy had been performed previously and the terminal illness was known, confirms the suggested association of biliary and cardiovascular disease (chart 8). Cardiac disease and apoplexy together accounted for more than 45 per cent of the deaths of these patients. Data obtained from a life insurance company give the incidence of these two causes of death as slightly less than 20 per cent among persons of similar ages. Subsequent disease of the biliary tract accounted for almost 5 per cent of the deaths in our cases and angina pectoris for about 3 per cent; the latter was practically identical with actuarial statistics. It might be suggested that if operation had been performed on the biliary tract years ago, disease would *no longer exist in this portion of the body*, and therefore deaths from cardiac and vascular disorders were not attributable to the influence of biliary disease. Lesions had existed in the biliary tract for some time before surgical treatment was employed, however, and unappreciated changes undoubtedly existed for years following operation, even in the absence of the gallbladder.

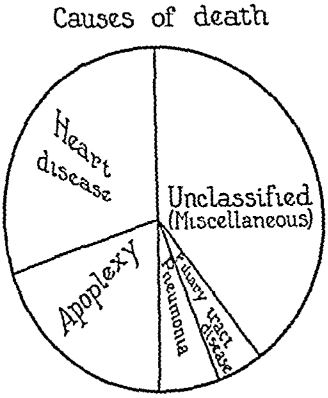

Chart 8.—The cause of death of 65 patients following operations on the biliary tract, all except 7 of which were cholecystostomies

COMMENT

Although cholecystectomy is now generally preferred for primary disease of the gallbladder, certain surgeons still perform cholecystostomy in a considerable number of cases. Our data indicate that a greater percentage of good results followed the former operation. Ordinarily the gallbladder is removed except in the presence of certain definite contraindications. If the patient is an extremely poor surgical risk, as in the presence of jaundice or a small atrophic liver, if it is anticipated that the gallbladder will be needed because of disease of the common bile duct, and occasionally if there is too much infection surrounding the gallbladder, cholecystostomy will often be preferable to cholecystectomy. If cholecystectomy is properly performed the immediate risk is probably no greater than surgical drainage of the organ, except in the cases mentioned.

During 1931, cholecystectomy was performed at the Mayo Clinic in 579 cases for chronic cholecystitis with a mortality of 1.7 per cent. If it is necessary to open the common bile duct, we feel that primary closure is never advisable. A variable period of drainage with a T-tube, ranging from three or four weeks to a year or more, depending on the lesion encountered, has given satisfactory results. When this type of drainage is employed, complete control over the flow of bile is maintained, as it may be drained externally through the long arm of the tube to the outside, or the tube may be clamped off, thus forcing the bile down into the duodenum. If it is considered desirable, fluids may be administered through this tube. A postoperative stricture of the duct does not result from the use of the tube, nor is there any danger of a persistent biliary fistula, provided patency of the common bile duct is established at the time of the operation.

THE CONSERVATIVE TREATMENT OF CHOLECYSTITIS

J. TATE MASON, M.D.
AND
J. M. BLACKFORD, M.D.
SEATTLE

The past decade has given us a wealth of new knowledge concerning the functions of the liver, gallbladder and biliary ducts. Because of this added knowledge of the factors influencing these functions, the immediate hospital mortality of 6 per cent noted in the earlier groups of patients operated on for chronic cholecystitis has been reduced to less than 2 per cent in later groups. We now know that a diseased gallbladder is almost always accompanied by inflammatory changes in the liver and in the biliary ducts, with resulting damage to liver function.

The damaged liver functions best with a high glycogen reserve. Dextrose by mouth passes through the portal circulation and is quickly stored as hepatic glycogen. The excess reaches the general circulation and is stored as muscle glycogen, not readily available for vital functions because it is not so readily released. For this reason apparently, ingested dextrose is actually more efficient than intravenous dextrose in building up vital glycogen reserves. Also intravenous dextrose given rapidly in large doses frequently spills over into the urine; such excess is not stored within the body. Furthermore, patients with livers damaged by obstructive jaundice usually become much dehydrated. If dehydration has developed, it must be relieved before the liver can store glycogen effectively, and even after relief of dehydration the capacity for hepatic glycogen storage returns slowly.

The schematic drawing shows how sodium chloride corrects acidosis or alkalosis if the kidneys are functioning properly. In alkalosis the administration of sodium chloride results in a retention of the chloride and an excretion of the sodium. In acidosis the reverse is true. If ketosis exists, give dextrose with sodium chloride. If the kidneys are not functioning properly, stimulate kidney function by giving 15 per cent dextrose in distilled water before using sodium chloride (Ravdin).

Mann has shown that animals with damaged livers are kept alive much longer on a carbohydrate than on a protein diet. Hence the patient having a damaged liver, or suspected of having such damage, should have a diet rich in carbohydrates and low in proteins. The low protein intake reduces the strain on the liver of having to exercise its detoxifying powers on the split protein products of digestion. We must realize that any change of mechanism, whether due to hepatic cell damage or to chemical activity, which depletes the liver of its glycogen reserve increases the operative risk. Patients with a normal blood chemistry will be found to stand operation with the least shock. These well known facts must be taken into consideration in the surgical and medical management of the disease.

It may seem untimely, with our recent advances in the knowledge of hepatic function, pathology and diagnosis, to advise conservatism in the surgical treatment of cholecystitis. We fear that occasionally surgical relief is advised because of refinements in the

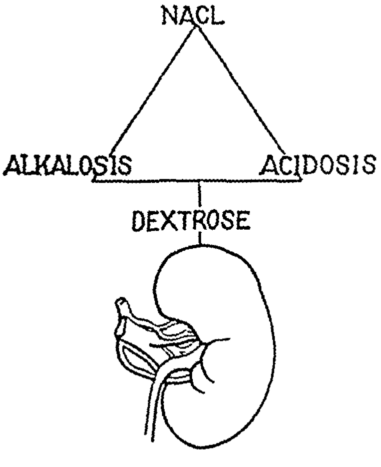
interpretation of symptoms, together with newer methods of objective diagnosis of gallbladder disease, rather than because of the former clinical reasons for advising operation, i. e., prolonged and distressing clinical symptoms. We have found that in chronic disease of the gallbladder and biliary passages clinical symptoms may be entirely absent. If symptoms are present, they may, in a definite percentage of patients, be relieved by simple medical treatment.

Every surgeon occasionally sees advanced gallbladder disease at operation which was unsuspected clinically. Conversely, he is frequently uncertain whether or not the exposed gallbladder is actually diseased. Frequently small gallstones and gallbladder sand are overlooked in the tense gallbladder seen in the fasting patient at operation. Recently in our clinic we have given, as a routine procedure, a glycerin emulsion of egg yolk and lecithin with glycerin and alcohol by mouth one hour before anesthesia.[1] We have thus greatly facilitated surgical palpation of the gallbladder by having it partially empty, and much to our gratification, in these patients the small intestines are usually collapsed, resembling the condition that is seen following a spinal anesthesia. We believe this procedure is contraindicated in definitely diseased gallbladders, as two of our patients with advanced gallbladder disease had attacks of colic one-half hour after this emulsion was administered.



Schematic drawing showing how sodium chloride corrects acidosis or alkalosis if the kidneys are functioning properly. (After Ravdin.)

Several years ago Blackford and Dwyer reported that gallbladder disease was found twice as frequently as peptic ulcer and gastric cancer combined, and that it was the most common organic cause of dyspepsia. The autopsy observations of Stewart, Crump and Mentzer have shown that cholecystitis is present in as high as 60 per cent of people over 40 years of age, and that gallstones are present in approximately one out of every five. We have found clinically that the condition in only a little over 6 per cent of all patients above 20 years of age admitted to the clinic has been diagnosed as gallbladder disease and for only 20 per cent of those complaining of stomach trouble has this diagnosis been made. Yet these autopsy observations show that many times this percentage of cholecystopathies are found at routine autopsy. We have had occasion to study 600 histories of patients suffering from well defined chronic cholecystitis. There were approximately twice as many women as men in this series. The familiar saying that gallbladder disease usually occurs in women who are fair, fat and 40 has not been true in this series except in part. The average age of the patients when seeking relief was approximately 45 years.

Until very recently we have considered acute pain as a cardinal symptom of disease of the biliary tract. A few years ago we hesitated before arriving at a diagnosis of gallbladder disease without this as the chief symptom. In this series, localized pain or soreness of varying degrees was a common complaint, but only 18.5 per cent of the patients gave a history simulating that of one or more attacks of gallstone colic.

Approximately three fourths of the patients of this series sought relief on account of chronic gastric disturbances, and in over half of these the gastric symptoms had persisted for more than ten years. These disturbances consisted first of food selection, which was the most frequent complaint. The foods most commonly avoided were those that were rich and highly seasoned, fried meats, cooked cabbage and raw apples. The next most annoying complaint was of gas and a feeling of fulness in the epigastrium after meals.

The gastric analysis was recorded in 402 cases. In more than half of these patients it was found that free hydrochloric acid was absent from the gastric contents or was definitely below normal. In only 6.7 per cent was free hydrochloric acid above normal. We hesitate in the presence of a hyperacidity to make a diagnosis of cholecystitis on a patient presenting a history of chronic indigestion.

SURGICAL FOLLOW-UP STUDY

This group of patients is composed of those who had their gallbladders removed from five to fifteen years ago. They were suffering from well defined chronic cholecystitits, without complications. Thus those patients with acute cholecystitis, empyema, jaundice or carcinoma have not been included. Regarding the relief of symptoms of pain by cholecystectomy, 83 per cent considered that the operation had relieved 75 per cent or more of their previous complaint. Fifty-six per cent stated that they had been completely relieved of all their old symptoms. Thirteen per cent continued to have symptoms as before, and 4 per cent had no relief.

Dyspepsia brings more patients with disease of the gallbladder to the physician than any other complaint. Consequently the degree of relief of this condition is a fair index as to the benefit derived from removal of the gallbladder. In answer to the question regarding this condition, 73 per cent stated that their digestive disturbances were greatly relieved, 18 per cent partially improved, 7 per cent unchanged and 2 per cent worse.

Gas and belching have been stated to be the most common and most annoying complaint with most people with disease of the gallbladder. After operation these symptoms were either absent (37 per cent) or markedly relieved (46 per cent) in 83 per cent; no change was noted in 12 per cent, and 4 per cent stated that they considered themselves worse following the operation.

The continued absence of free hydrochloric acid in the gastric content is the cause of the failure of some patients to receive much relief of their digestive disturbances following cholecystectomy.

Food selection is another frequent complaint, as previously noted. In answer to the question as to whether or not the removal of the gallbladder permitted these patients to eat without distress certain foods that they could not eat before, 68 per cent replied in the affirmative. Many patients were very emphatic in their statements relative to this question, affirming that they could now enjoy many foods that would previously have caused them great distress. Thirty-two per cent stated that they noticed no particular difference following the operation, and only 2 per cent felt that they were worse in regard to food selection than they had been previous to the removal of the gallbladder.

---

[1] This emulsion was suggested by Dr. Lester Levyn of Buffalo as an aid in roentgenology in his article, "An Effective Gallbladder Stimulant to Supplant the Fat Meal," Am. J. Roentgenol. 26: 904 (Dec.) 1931.

Colic, which is considered a common symptom of patients with disease of the biliary tract, occurred in 18 per cent of the patients before surgical and medical treatment had been instituted. We find that 17 per cent still reported colic after surgical treatment, but that most of these patients had only one or two attacks and these in the first year following their operation. Five years ago we were not draining the common and hepatic ducts nor investigating for stones as often as we are today. This may be the reason for this rather high percentage of patients having colic following their operation. The exact cause of gallbladder and duct colic not due to calculi has not yet been definitely established, as many of these gallbladders and ducts did not contain stones, only 45 per cent of the total series being found at operation to have stones.

MEDICAL FOLLOW-UP STUDY

The results in the patients who received surgical relief were most satisfactory. Yet we were impressed with the fact that there was a considerable series of patients with clinical cholecystitis who had been advised medical treatment or who had refused surgical treatment and hence were receiving medical treatment of some kind. Two hundred patients were selected for this study who had elected or had been advised medical treatment. We have been surprised at the infrequency with which delay has resulted in emergency operation or disaster. These 200 cases represent a 60 per cent successful follow-up of probable, typical and proved cases of gallbladder disease available for study after an average of nine and a half years. The average length of history was nine years, so the total average duration of history from the beginning of symptoms to the present is eighteen and one-half years. All available methods of follow-up study have been used; we have found it vastly more difficult to follow up medical than surgical cases. Diagnosis is assumed to be approximately 90 per cent correct, for these cases were studied by a group of careful clinicians, all usual methods of studying gastro-intestinal complaints being used, and cases with questionable diagnosis have been discarded. Most of these patients were studied before cholecystograms were available, but late in the series this method was used. Immediate operation was advised but refused in one third of these cases. A trial of medical treatment was advised in two-thirds, but it was always stated to the patient that operation was advisable later if relief was not obtained promptly by medical treatment.

Medical Treatment.—The patient with dyspepsia due to gallbladder disease has usually found, as mentioned previously, that certain rich and tasty foods disagree, that overloading the stomach brings on trouble and that high seasoning, fried foods and alcohol are often distressing. Naturally he tries to avoid the things that he knows make trouble. By medical management we mean the use of a diet list with general instructions and elimination of foods that usually disagree with such patients. We have advised periods of the use of morning saline, usually sodium phosphate; biliary salts before meals, lately combined with oleic acid; and relief of constipation. Alkalis have occasionally been used. Infective foci have usually been relieved, and we have laid emphasis on reasonable physical exercise. Medical biliary drainage (Lyons-Meltzer) has not been used for treatment.

Such a regimen has been instituted in all cases, but has been followed only as the patients cared to follow it. Treatment has not been supervised or followed closely.

The results of the medical study can be briefly stated. One third of these patients, under simple medical treatment, became symptom-free. One-third came to operation from three to five years after the diagnosis was made. One-third, because of the continuation of their symptoms, should have come to operation.

CONCLUSIONS

This study has confirmed our impression that in well defined chronic cholecystitis not relieved by medical treatment the operative results are most satisfactory. However, contrary to usual surgical advice, chronic cholecystitis may, in approximately one third of the patients, be successfully treated along medical lines. The risk of developing a surgical emergency or calamity while under medical treatment is not greater than is the risk in the best elective gallbladder surgery. Patients who have allowed their gallbladder symptoms to go on for a number of years until their gastric acids have become low or absent, with definite and permanent pathologic process of the liver and biliary ducts, cannot expect as complete relief from cholecystectomy as if they had accepted immediate operation. Hence we believe emphatically that when medical management fails to relieve promptly then operation should be urged on the patient. We wish to emphasize the fact that patients with acute cholecystitis, empyema, jaundice or carcinoma have not been included in this study.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. JUDD AND PRIESTLEY AND DRS. MASON AND BLACKFORD

DR. R. L. PAYNE, Norfolk, Va.: I took the opportunity to go over my gallbladder cases through my follow-up methods, and some of the facts that I deduced have been worthy of comparison with those presented by the authors. I was amazed to find that the results after cholecystostomy in the early years were much worse than those reported by Drs. Judd and Priestley. Cases in which a second operation was performed were a great deal more frequent. Drs. Mason and Blackford presented a most interesting series of cases in which one third of the patients were relieved by medical treatment and two thirds by surgery. I have no medical series to compare with these, but I have a series of definitely proved cases of cholecystitis, proved at operation when cholecystostomy was done, that would indicate that 76 per cent of these cholecystostomy patients required second operations. In one series of fifty cases done between 1907 and 1913, by an accurately followed record, thirty-eight patients were reoperated on for trouble in the gallbladder or common ducts. In the early years, cholecystostomy was done almost as a routine and removal of the gallbladder was rarely done. In later years, in 545 cholecystectomies, 80 per cent of the patients have received satisfactory results. I was astounded to find that only 8 per cent of this series showed any common duct problems at the time of primary operation, and that, in 1 per cent of the 545 cholecystectomies, common duct complications developed after the gallbladder had been removed. In the last two years I have come to feel that if the operator does not believe that cholecystectomy can safely be performed in acute severe fulminating cholecystitis it would be to the best interests of the patient if the gallbladder was split open and destroyed by a strong chemical or the actual cautery, feeling that in the final analysis this would prevent a second operation. However, I have observed in many of these acute cases that in nearly every instance the process is well walled off from the rest of the abdomen, and I feel that if the enucleation of the gallbladder is carried out carefully and within the walled-off area, cholecystectomy at that time is the best procedure, even though one might have to put a clamp on the cystic pedicle and be satisfied to leave it there and to pack the bleeding, oozing liver crater in order to finish and get out in a hurry. When one realizes that with all bad cholecystitis there is a complicating hepatitis, and remembers that we are told by Dr. Judd and others that this hepatitis has a definite tendency to repair after removal of the gallbladder, we must conclude, with Dr. Royster, that cholecystectomy is synonymous with surgical vision, for it is doing one operation to prevent another.

Dr. Frank H. Lahey, Boston: I rise to make two particular points in connection with this paper: (1) to adduce some evidence to the effect that earlier operation will influence mortality and end-results in gallstones; (2) that common duct stones are much more frequent than they have heretofore been thought to be. Up to 1926 my associates and I had operated in 619 gallbladder cases; we had opened the common duct and searched for stones in 12 per cent of these cases. This netted a discovery of common duct stones of 8 per cent. That number of cases in 1931 has been brought up to 1,306. Last year we opened the common duct and searched for common duct stones in 41 per cent of the cases. That netted a discovery of common duct stones of 19 per cent. Previous to 1926 we undoubtedly left a stone in the common duct in approximately one in every ten cases in which operation was performed. The mortality in the cases up to 1926 was 5.4 per cent. The mortality in the group from 1926 to 1931 with an increased exploration of the common duct is 2.2 per cent. It does not increase the mortality in cholecystectomy, in gallstone operations, to open and explore the common duct; it decreases it. Of all the patients who had common duct stone operations, the mortality was 13.3 per cent. Therefore, two conclusions must be drawn. One is that long-standing gallstones increase the number of cases of common duct stone, and that when one waits to operate on these patients until they have common duct stones the mortality will be high. Our medical friends must overcome the complacency with which they permit patients to go through repeated attacks of gallstone colic. They must learn that if these patients are operated on while the stones are still in the gallbladder the mortality will be low and the end-results will be much improved. Thirty-nine per cent of all the patients in whom we found common duct stones did not have jaundice, and we must learn as surgeons that we do not want to wait until they have jaundice to make a diagnosis of common duct stones; we must learn that in the entire absence of signs of common duct stones, on only secondary indications, such as dilated ducts and thickened and contracted gallbladder, we must open common ducts and not depend on palpation alone. Common duct stones are overlooked at the ampulla of Vater, and frequently they cannot be felt within the thickened head of the pancreas; they must be searched for. If one will open the common duct and search for them in all suspicious cases, one will more than double the incidence of discovery of common duct stones, and when one does discover them and removes them one will not increase the operative mortality, one will lower it and improve the end-result. But the important point I wish to make is that we must urge our medical friends not to carry these patients through repeated attacks of gallstone colic with morphine and other sedatives. They must learn that it is delay on their part or the patient's part which makes the ultimate high mortality and bad results.

Dr. Moses Behrend, Philadelphia: There are three points in the paper of Drs. Judd and Priestley to which I should like to refer. The first is that cholecystectomy is a better operation than cholecystostomy. This has been known for years, but it is wise to call attention to the subject again. There has been less recurrence of symptoms as a result of the operation of cholecystectomy than as a result of cholecystostomy. A important point was brought out in the paper of Drs. Judd and Priestley with respect to the relation of jaundice to cholecystectomy. In all clinics the surgeons develop certain axioms, and one of our axioms is that the gallbladder should never be removed in the presence of jaundice. The changes that occur in the blood in jaundice are well known, and that is one of our reasons for not removing the gallbladder. It was rather surprising to hear Drs. Judd and Priestley say that they had less trouble in those cases in which there were no stones. My experience has been to the contrary; more trouble results following operation in cases without stones than in those in which stones are present. I thought that was the experience of the majority of surgeons. When there are no stones present, these patients develop a certain number of nervous symptoms which somehow or other are not eliminated as the result of operation. An important point touched on was the relation of the gallbladder to heart conditions. In a recent paper before the seminar of the Philadelphia County Medical Society I noted that my experience corresponds exactly with that of Drs. Judd and Priestley. There is no question that there is a profound relationship between infection of the gallbladder and cardiac disease. More than ten years ago Dr. Joseph Wolffe and I did some work on the relation of cardiac disease to gallbladder infection, and we found that after the gallbladder is removed the heart recovers in a certain percentage of cases, whereas in others it remains permanently damaged. I must take exception to the statement of one of the discussers concerning acute gallbladder disease and the walled-off area. I think that one should never remove the gallbladder, even if it is in this walled-off area. If one has made a mistake in diagnosis and operates on an acute gallbladder under a diagnosis of acute appendicitis, the gallbladder should always be drained and not removed. The removal of the gallbladder in acute infections is entirely too hazardous a thing to attempt, on account of the infection that will permeate the entire system.

Dr. Willard Bartlett, Jr., St. Louis: I have a little further evidence to add to the remarks made by Dr. Lahey. The changes in the liver and in the pancreas have been well known, of course, in chronic biliary infection. Drs. Judd and Priestley have emphasized the appearance of cardiovascular complications. Little attention has been paid, however, to complications in the kidney in conjunction with long-standing gallbladder disease. I am about to report a series of five cases of anuria occurring with cholecystitis. This has been associated in each case so far with jaundice, and whether it is the result of long-standing jaundice or of long-standing infection I am uncertain at present. These cases have occurred in persons in the fifties and over, without exception. It is impossible to say that there has not been not a complicating but simply an additional chronic nephritis in these cases. In two of them, however, I have known that two weeks previous to the onset of the anuria the urine was microscopically and chemically normal, the blood nonprotein nitrogen was normal, and the excretion of phenolsulphonphthalein was above 75 per cent. One of the five patients recovered. All of them, under treatment with 50 per cent solution of dextrose given intravenously, and salyrgan (used very cautiously) showed a temporary improvement. Since observing these cases I have tested all patients with chronic cholecystitis for kidney function, both by phenolsulphonphthalein excretion and by concentration tests. I have definitely observed, and will report later, that in certain patients who are jaundiced or have recently been jaundiced, there is a constant inability to excrete phenolsulphonphthalein satisfactorily and to concentrate the urine. In such cases I have not done a cholecystectomy but have preferred to do cholecystostomy, maintaining the drainage of the biliary tract by the Pezzer catheter (mushroom catheter) in the gallbladder until such period as I felt cholecystectomy could be safely undertaken. That has ordinarily been from three to six months. I have had no difficulties with loss of bile. There are a good many ways of managing that satisfactorily. When these patients who have had preliminary cholecystostomy have returned for cholecystectomy, they have shown a definite improvement in their ability to concentrate their urine and to excrete phenolsulphonphthalein. I present this as an additional reason for not allowing patients to go past 50 years of age, the deadline, more or less, for elective surgery, carrying their chronic abdominal infection into that age group.

Dr. I. S. Ravdin, Philadelphia: These papers and discussions have shown that additional information is required regarding the chemical changes that occur in the bile in gallbladder disease. During the past year my associates and I have been studying the chemical changes that occur in the bile in the human gallbladder. It is only from data of this type that one can gain additional information on the pathologic changes that occur in gallbladder bile after infection of the biliary system. In the first place, it is important to obtain information that will permit one to draw deductions from physiologic observations on the biliary tract of the dog in comparison with that of the human being. Studies that we have made convince us that in most particulars the concentration of the chemical constituents of the bile in the gallbladder of the human being are the same as those we have described for the dog. The normal bile that we have studied has come from patients who did not have gallbladder disease. In the patients with chronic cholecystitis without stones but in whom gallbladder visualization was obtained by roentgen rays, there is a marked decrease in the bile salt concentration in the bile found in the gallbladder. In the group with chronic cholecystitis with stones but in which gallbladder visualization was also obtained, one finds a lower concentration of bile salts than in the second group, a slightly lower concentration of calcium and an increase in the chloride concentration. In the last group, the cases of chronic cholecystitis with stone in which the gallbladder was not visualized, calcium is not concentrated at all, the chloride concentration is extremely high, and in the majority of instances there is no bile salt present. This shows a progressive change in the chemical constituents of the gallbladder bile with progressive alterations in the pathologic lesion. In a few patients having common duct obstruction from stone, the bile was examined some days after the introduction of a T-tube in the common duct. In every instance one finds that after an interval of frequently three weeks, when the bile looks normal, there is still no bile salt present in the bile coming from the liver as determined by the Gregory-Pascoe reaction, so that the liver as the result of the obstruction is damaged for a longer period than we have previously been led to suspect. This emphasizes a point which Drs. Judd and Priestley brought out, that as yet we do not know the length of time during which the liver remains damaged after common duct obstruction.

DR. J. TATE MASON, Seattle: I should like to call attention to the fact that in the paper of Drs. Judd and Priestley and in much of the discussion, mention has been made several times of complications affecting the common duct following cholecystectomy. The anastomosis between the common duct and the duodenum has been difficult. Anastomosis is not difficult except in a slight degree when an opening is made between the gallbladder and the stomach or from the gallbladder to the duodenum, but I now believe that, when these artificial openings remain patent, in the course of a short time infection is likely to ascend from the viscus through the biliary passages and into the liver, resulting in a chronic hepatitis, which, in turn, is followed by multiple abscesses of the liver. I do not believe that this ascending infection occurs when the anastomosis is made between the common duct and the duodenum and that in patients suffering from stricture of the common duct or benign or malignant tumors of the ampulla of Vater a choledochoduodenostomy is the most satisfactory operation that can be performed. I will present a simple way of anastomosing the common duct to the duodenum: First the common duct is exposed just above the upper border of the duodenum. Two or three, or occasionally four, sutures are then placed from the duodenum to the duct. These form the posterior line of suture of the anastomosis. Just in front and close to the suture line, a small opening is made in the duct and also one in the duodenum. Through these two openings, one above into the common duct and one below into the duodenum, a T-tube is placed which is of approximately the same size as that of the common duct. The lower arm of the tube is in the duodenum and the upper in the common duct, while the stem of the tube of course hangs outside the abdominal wound. The opening in the common duct and duodenum is then sutured up around the stem as closely and as neatly as can be done, with interrupted sutures. During the time that these sutures are being placed, by gently tugging on the stem the surgeon can bring the whole field of operation well up within the wound. When the suturing is completed, the stem of the T-tube is cut off at the point of its junction with the two arms, or as near this point as possible. The small opening left by the stem is sutured over with two or three interrupted sutures, and then to prevent the tube that remains from hanging in the anastomosis for too long a period, the tube is gently pushed down into the duodenum until only about a third of its length is hanging in the anastomosis. This tube passes through the intestinal tract in from five to six days. This method of anastomosis requires only ten or fifteen minutes and hence is very simple, in contrast with what has sometimes been found to be a very difficult procedure.

THE MANAGEMENT OF HEMORRHAGIC PROBLEMS IN INFANCY AND CHILDHOOD

I. NEWTON KUGELMASS, M.D.
NEW YORK

Hemorrhagic disturbances abound in clinical confusion. The loss of "life" blood alarms parents, the appearance of petechiae perplexes physicians, and a hemorrhagic history preoperatively petrifies surgeons. The hemorrhagic state is ever a problem. Manifest bleeding is precipitated and yields more readily to immediate control than to subsequent prevention, but latent hemorrhage is elusive, defying detection even more than a diagnostic differentiation. Children reveal hemorrhagic symptomatology that is too heterogeneous to be typical, too recurrent to withstand diagnostic delay, too dependent on systemic disease to be primarily hemorrhagic.[1]

The hemorrhagic status of a patient is best evaluated clinically in terms of degree of function of the vascular endothelium and its blood content. Although chemical changes are present in both in most hemorrhagic disturbances, the one or the other necessarily dominates the picture. It is only in truly hereditary hemorrhagic disease that absolute deficiency in the vascular system or in one of the clotting components is characteristically unitary in its pathogenesis. But the number and variety of acquired hemorrhagic diseases are legion. They are necessarily characterized by varying degrees of functional change in the blood channels as well as in the blood-clotting components expressed by the equilibrium:

$$\text{Reticulo-Endothelial System} \rightleftarrows \text{Blood} \rightleftarrows \text{Vascular System.}$$

Typical hemorrhagic problems are therefore limited, while the majority reveal varied transitional changes in vascular phenomena and clotting components. One of these factors constitutes the controlling factor. Its determination is indispensable among the criteria essential for final diagnosis. Clinical symptoms alone never suffice for arriving at the exact nature of the underlying condition productive of the hemorrhagic disease. Besides the family history, the past hemorrhagic status, the constitutional susceptibilities, the nutritional regimen, the physical examination, the current therapy and the blood picture, several simple tests are made for the determinations of the blood-clotting and vascular functions.

DIAGNOSIS AND TREATMENT OF HEMORRHAGIC DISEASES: DISTURBANCE IN THE BLOOD CLOTTING FUNCTION

The hematic group of bleeding problems constitutes the essential hemorrhagic [illegible] hemorrhagic disease of the new-born, hered[illegible]topenic purpura and the diseases of the bone marrow, spleen and liver. Each is characterized by a functional deficiency in one of the clotting components as the controlling factor in the pathogenesis of the hemorrhage. Each clotting factor congenitally deficient is indicative of a specific hereditary hemorrhagic disease. Each disease is amenable to control to the extent that the deficient factor is replaced or regenerated. Bleeding

Read before the Section on Pediatrics at the Eighty-Third Annual Session of the American Medical Association, New Orleans, May 13, 1932.

Because of lack of space, this article is abbreviated in THE JOURNAL. The complete article appears in the Transactions of the Section and in the author's reprints.

[1] Kugelmass, I. N.: Arch. internat. de physiol. 21: 139, 1923.

in these cases tends to be prolonged and continuous once the vascular integrity is disturbed. But until the provoking condition precipitates bleeding many of these and associated conditions constitute potential hemorrhagic disease determined not by symptomatology, but by accidental study of blood-clotting function.

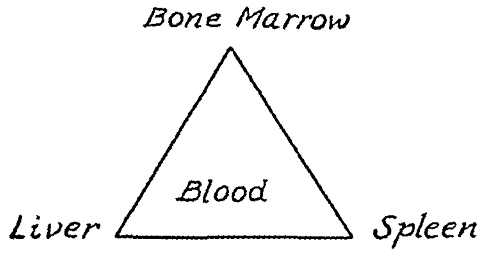
Potential Hemorrhagic Disturbances.—Bleeding is not an infrequent symptom in apparently well and active children. To be sure, trauma, infection, drugs and even insect bites induce all forms of benign hemorrhagic manifestations apart from hemorrhagic disease. But there is a group of well children in whom nosebleeds, black and blue spots and other hemorrhagic manifestations are either indicative of potential hemorrhagic disease or, more generally, of diminished blood-clotting function, since the vascular endothelium suffers no disturbance in nutrition in severest anemia or hydremia. The results of physical examination may be negative and clotting time prolonged or normal but the clotting components diminished in prothrombin, fibrinogen or platelets. We[5] have observed in the last five years that these clotting components may be altered by dietary regimen.

Protein and fat tend to increase the concentration of the blood-clotting components, while carbohydrates and minerals tend to decrease it. We[5] have therefore devised a "clotting diet" high in protein and fat, acid forming and low in vegetables and carbohydrates and a "bleeding diet" high in vegetables, carbohydrates and water, base forming and, of course, minimal in protein and fat. The effect of these diets on the clotting function has been demonstrated in animals to shift in the direction of increased bleeding or clotting after a week of such a regimen. Similar results are attained in children whose tendency toward bleeding is discovered accidentally or preoperatively. Our surgical staff has been particularly concerned about the application of these dietaries preliminary to operations to prevent postoperative bleeding in some and thrombosis in others, as predetermined by the index of blood-clotting function.

Hemorrhagic Disease of the New-Born.—Melena is a self-limited symptom complex distinct from other hemorrhagic disturbances in the new-born. It is a transient though severe reaction of the new-born to chemical injury of the reticulo-endothelial system. Its manifestation of bleeding from the mucous membranes may simulate veritable diseases—syphilis and sepsis during the first days of life and purpura, hemoglobinuria and visceral anomalies during the first weeks of life, but the mechanism of melena is less deep-seated; it is self-compensating and even preventable. Potential hemorrhagic disease may be recognized on the first day of life by the prolonged clotting time.[6] This reveals injury in the formation of the blood-clotting substances, prothrombin or fibrinogen. Their diminution is brought about by anesthetic drugs administered during labor, by postnatal hemolyis of red cells as well as by prenatal deprivation of protein and fat on the part of the mother.



The hemorrhagic triad.

Though a multiplicity of factors may be operative in the development of melena neonatorum, the daily injection of 30 cc. of human blood intravenously from the first day of life arrests oozing within twenty-four hours. I have observed in the course of my studies on the nutrition of the new-born that the oral administration of gelatin from birth is preventive of hemorrhagic disease. The feeding of 3 per cent gelatin solution at two hour intervals has reduced the average clotting time of new-born infants from nine minutes to two minutes in about 200 babies, with an equal number of controls, and produced a corresponding rise in clotting function. I have not observed a single case of hemorrhagic disease of the new-born throughout the year during the administration of this modified

solution, which was primarily devised for the purpose of preventing loss of weight in the new-born child.

Prenatal prevention of potential hemorrhagic disease in the new-born is another approach. I[7] have been privileged to see recurrent melena neonatorum in babies born of the same mother, T. N., under the obstetric care of Dr. Tritsch at the Fifth Avenue Hospital. The first four pregnancies terminated in death from hemorrhagic disease, as substantiated by postmortem examination. It was during the fifth pregnancy that a prenatal attempt was made to prevent the anticipated severe melena. The mother's blood showed a concentration of clotting components characteristic of hemorrhagic disease in the new-born. She was given dietary very high in protein, in contrast with her usual low intake of protein, limited during previous pregnancies because of hypertension. The blood-clotting picture became adequate, and a normal infant was delivered at term. The baby has been under my observation for four years and has been perfectly well since birth. Encouraged by her favorable fifth pregnancy, she proceeded to a sixth, but refused to be under rigid nutritional supervision, and was delivered of an infant with melena, proved by postmortem examination in the same institution.

Table 2.—*Increase in Blood Clotting Function on a High Protein Dietary in Potential Hemorrhagic Disturbances* *

* There was an interval of one month between determinations.

Essential Thrombocytopenic Purpura.—This is a benign disease of the reticulo-endothelial system. It is primary in the spleen, where platelets are destroyed, and secondary in the bone marrow, where lesions interfere with normal platelet formation. The marked reduction in the number of blood platelets and their alteration in size and structure bear no definite relationship to the severity of the bleeding, the bleeding time, the impaired clot retraction and the diminished capillary resistance. This blood picture appearing suddenly in an apparently well child, without cause for the hemorrhagic state, and the posthemorrhagic anemia and leukocytosis determine the diagnosis. These criteria characterize the disease in all grades of severity, in the acute fulminating type, in the transient attack and in the chronic latent course, whether the bleeding is limited to a single source or is widespread.

Effective control of bleeding in acute cases or prevention of bleeding in the chronic problems depends on procedures for increasing the concentration of blood platelets. All other methods are wasteful and without effect. In emergencies, the intramuscular injection of 50 cc. of whole blood, requiring no typing, increases the platelets and arrests hemorrhage. But large transfusions from a suitable donor not only supply platelets but actually stimulate platelet generation. They must be repeated every fourth day, paralleling the average life of infused platelets. Feeding high in fat and rich in vitamin D and ultraviolet irradiation, particularly after anointing the body with wool fat, produce transient rises in platelets and help to tide over an acute problem.

Persistent bleeding in 70 per cent of chronic cases is permanently relieved by splenectomy. It is unfavorable in acute conditions in which the mortality is 80 per cent in comparison with 8 per cent in the chronic cases. The operation must be properly timed for obtaining favorable postoperative prognosis. Preliminary roentgen irradiation of the spleen produces a leukopenia which is an unfavorable prognostic omen. Splenic enlargement is not a necessary criterion for operation, although the removal of massive spleens has saved lives from being lost through uncontrollable hemorrhage. Following splenectomy the platelets may rise to a million and then return to normal levels in patients in whom platelet destruction has been the mechanism. But in those in whom platelet formation has been retarded, the postoperative rise in platelets is less marked, and the subsequent level attained is necessarily low.

Symptomatic Thrombocytopenic Purpura.—Purpura is a hemorrhagic symptom widespread among many diseases. Besides the essential type, it may be a manifestation of clinical syndromes associated with diminution in blood platelets in diseases of the bone marrow, spleen and reticulo-endothelial system as a result of infection or intoxication, or it may be a symptomatic expression of mere capillary injury in the course of systemic infection, chemical intoxication, allergic offense and a variety of other capillary-toxic conditions. In the one group of conditions, the blood picture is a revelation of injury to the blood cells, whereas in the other group the blood picture is usually normal. Purpura therefore becomes primarily a problem for careful clinical differentiation between the varied types of diseases characterized by either clotting or vascular dysfunction. Diagnostic differentiation makes all the difference between benign and malignant diseases, effective and fancied therapy, favorable and fatal prognosis.

Table 3.—*Hemorrhagic Disease of the New-Born*

Name	Day of Onset	Duration of Bleeding, Days	Clotting Time	Bleeding Time	Clot Retraction	Tourniquet Test	Prothrombin	Fibrinogen	Antithrombin	Platelets	Lysis	Index
C. W.	Third	1	5	2	+	—	1.0	0.2	1.25	300,000	43	0.3

A. G.	Second	2	120	5	+	—	0.1	0.4	5.0	180,000	40	0.01

Treatment of symptomatic thrombocytopenic purpura necessarily depends on the primary diseases. Splenectomy is indicated in Gaucher's disease and in constitutional hemolytic anemia, because the purpura mechanism is similar to that of essential thrombocytopenic purpura. But the great variety of other conditions is the result of destruction of blood-forming organs by intoxication, infection or infiltration resulting in malignan [illegible] Some infectious diseases injure [illegible]akaryocyte mechanism. Primary blood diseases in addition affect the formation of other blood cells. Certain drugs likewise reduce myeloid elements of the blood. These myelotoxic conditions are malignant, resisting all forms of therapy. But the associated vascular injury and infiltration may be influenced to arrest bleeding by diminishing capillary permeability. The slow intravenous injection of 10 per cent calcium gluconate or chloride daily in 20 cc. amounts, supplemented by oral administration of calcium salts, is a transient therapeutic measure alternated with blood transfusions. But splenectomy is contraindicated.

---

[7] Kugelmass, I. N., and Tritsch, J. E.: Prenatal Prevention of Potential Hemorrhagic Disease of New-Born, J. A. M. A. 92: 531 (Feb. 16) 1929.

Purpuric problems are rarely patterned according to the textbook. Only purpuric children can illustrate how strikingly borderline diagnostic criteria may be.

Characteristic thrombocytopenic purpura with remissions developed in Dr. Marton's 8 year old boy, until splenectomy became imminent. When he came under my observation I found that he had been quantitatively deprived of protein and fat because of chronic eczema. As a last resort, a dietary high in protein and fat brought the platelets from 20,000 to 400,000, with the disappearance of purpura in 1927. Obviously, I am not advocating dietary specificity in thrombocytopenic purpura.

S. T. was admitted because of thrombocytopenic purpura with severe bleeding from the gums for five months, but without other hemorrhagic symptoms. Examination of the blood showed: hemoglobin, 28 per cent; red blood cells, 1,200,000, and white blood cells and differential count, normal. The platelets numbered 40,000, and the tourniquet test was positive. Systemic treatment of the severe Vincent's infection and transfusions of blood cleared up the problem, for which splenectomy was, of course, not indicated.

N. K., a boy aged 5 years, had had hemorrhagic otitis media, epistaxis and hematuria following tonsillectomy at 3 years of age, at which time the clotting and bleeding times were normal. Purpuric symptoms recurred for two years until admission to the hospital. Examination of the blood showed: clotting and bleeding times, normal; tourniquet test negative; platelets, 35,000, and white blood cells and differential count, normal. The spleen was not palpable. After treatment with a clotting dietary the platelets rose to 240,000, but fell with the remission of symptoms. Splenectomy brought the platelets to 415,000, with recovery.

M. S., a girl aged 11 years, was admitted to the hospital with repeated and severe epistaxis for a week. Epistaxis and excessive bruising appeared periodically for two years, requiring medical care. The clotting and bleeding times were normal. The tourniquet test was negative, and the platelets numbered 110,000. The spleen was not palpable. The blood picture was normal. The consensus was against splenectomy, but it was performed in another hospital under unfavorable conditions of uncontrollable hemorrhage four months later, with recovery.

Hereditary Hemorrhagic Diseases of Blood-Clotting Dysfunction.—Hereditary hemophilia, a clinical chimera for many a bleeding problem, is too rare a condition to cover so many hemorrhagic disturbances and is too well defined an entity to become a haphazard label of hemorrhagic confusion. Bulloch and Fildes have been able to authenticate only 44 hemophilic families of 273 reported in a century of literature since its classic description by Otto in 1803. The disease occurs exclusively in the male, with a typical familial bleeding pattern, and must not be confused with other familial hereditary hemorrhagic diseases afflicting females. It is transmitted through the female, although the mothers of our hemophilic boys showed normal blood-clotting function. It is characterized by prolonged duration of bleeding, even though the clotting time often is only slightly prolonged. It paradoxically shows a normal bleeding time, because the clotting function of the skin is greater than that of the mucous and serous membranes. Hemophilic blood shows the lowest index of blood-clotting function, with a normal or an increased number of platelets physiologically defective because of their strikingly great resistance.

Table 6.—*The Concentration of Clotting Components and the Index of Blood Clotting Function in Hereditary Hemophilia*

Case	Age, Years	Date	Prothrombin	Fibrinogen	Antithrombin	Platelets	Platelet Disintegration, per Cent	Index
C. M.	2	11/11/30	0.12	0.46	5.7	305,000	30	0.009
C. B.	4	3/ 5/28	0.33	0.64	4.1	370,000	32	0.05

Normal ..	....		1.00	0.50	1.0	250,000	50	0.50

Diagnostic criteria are not always clearcut in transitional hemorrhagic problems.

C. M., a boy aged 2 years, showed no tendency toward bleeding until many bruises appeared following trauma incident to walking at 11 months of age. There was no such history in three preceding generations of the family. The clotting time was six minutes, but the clotting index was 0.009 when the picture of the blood was otherwise normal.

D. B., a boy aged 6 years, with hemophilic joints, showed a clotting time of eleven minutes, a bleeding time of eighteen minutes, normal platelets, a positive tourniquet test and normal clot retraction. The father was allergic. A diagnosis of hemophilia with athrombopenic purpura was made.

G. M., a boy aged 10 years, had required repeated transfusions of blood following slight traumas since birth. He was under my observation for hemophilic arthritis two years ago. Recently bronchopneumonia with otitis media had developed, precipitating spontaneous bleedings from the nose and gums. Examination showed: clotting time, ten minutes; bleeding time, thirteen minutes; platelets, 60,000; spleen, enlarged, and tourniquet test, negative. The case was considered to show transient purpuric picture in hemophilia.

B. S., a boy aged 9 years, was admitted to the hospital as a "hemophilic" after three other hospitals had refused tonsillectomy because of prolonged clotting time. Hemorrhage had first occurred after myringotomy in infancy. Easy bruising followed slight trauma. There was no family history of hemophilia. The clotting index was 0.2, and was increased to normal by calcium therapy and clotting dietary. Tonsillectomy was performed without postoperative bleeding.

Hemophilic bleeding can be controlled but not cured. Mild bleeding may be stopped locally by applications of fresh raw meat, fresh blood or cephalin after the removal of useless clots, since pressure alone is contraindicated. All other hemostatics locally applied are ineffective. Severe bleeding may be checked for four days by the transfusion of whole blood from a suitable donor. Even an ounce of injected blood arrests hemorrhage, but the degree of subsequent improvement depends on the amount of blood given. Stored serum is ineffective in inhibiting clotting but an ounce of fresh serum arrests bleeding within a day.

Protein sensitization is beneficial in diminishing bleeding from superficial injuries as well as in abating recurrences. The child is sensitized to horse serum by subcutaneous injection of 3 cc. of serum. We have seen no difference between the use of diphtheria and antivenene serum. At the end of a week the child is given 2 minims (0.1 cc.) of the serum, injected intradermally, which demonstrates successful sensitization by the wheal formation. Intradermal injection should be repeated monthly for the maintenance of sensitivity, an effect primarily on the capillary system. The treatment is helpful in hemophilic arthritis, for which autogenous blood has also been given intramuscularly. Obviously, the sensitization mechanism is the same. It increases the recession of the hemorrhagic joint, which must be immobilized in a neutral position by means of plaster casts when necessary.

The prevention of hemophilia is a problem for eugenics. The course of the disease can be altered. Nature spares hemophilic new-born infants from the effects of birth trauma by the transmission of an abundance of female sex hormone into the infant's circulation. Thus it is that the disease does not become manifest until late in infancy, unless surgical intervention precipitates bleeding. The disease tends to ameliorate with growth, particularly after the endocrine adjustment of puberty. The absence of the female sex hormone in hemophilic persons has made its isolated preparation a therapeutic indication.[8] I have found that the injection of female sex hormone preparation alone or reinforced by anterior solution of pituitary produces no change in the concentration of the clotting substances from the levels characteristic of hemophilic subjects. I have observed that 500 mouse units of the hormone is necessary to increase the capillary resistance sufficient for it to reveal a negative test within two days in hemorrhagic diseases affecting vascular integrity rather than the blood-clotting content.

Our hemophilic boys with joint manifestations have benefited most during the year in that the periodic effusions were diminished. The hormone therapy has not diminished the tendency to bruising, but has decreased the tendency to bleeding following natural trauma. The avoidance of trauma by limitation of activity requires compensatory physical therapy to improve muscle tone. The maintenance of bodily warmth and vacations in warm climates appear, in addition, to alter favorably the course of the disease. The clotting dietary has produced no appreciable effect on the hemorrhagic status of hemophilic persons. Infection has been found to precipitate bleeding particularly into the skin and joints. Operative emergencies are safely carried out after preliminary transfusion.

Hereditary Thrombasthenic Purpura.—Typical manifestations of thrombocytopenic purpura may be simulated by this hereditary disease involving strikingly abnormal and functionally inactive platelets. It is a familial defect transmitted from generation to generation to both males and females. It is readily differentiated from hemophilia in this respect as well as in the blood picture. The number of platelets fluctuate in different members of these families from relatively low normal to high values. Abnormalities in their size, shape and staining qualities and failure of agglutination are characteristics common to all. As a consequence, the bleeding time is prolonged, the clotting time is normal, the clot retraction retarded, the tourniquet test positive, the spleen rarely enlarged and purpuric bleeding a common symptom.

Such was the case of a girl aged 10 years, who continued to bleed excessively despite splenectomy performed on the basis of supposed chronic thrombocytopenic purpura. She had had recurrent epistaxis and purpura since the first year of life. The mother, who bled mildly, died during childbirth. The son did not bleed. The patient was admitted to the New Jersey hospital for an emergency operation. Preoperative examination of the blood showed: hemoglobin, 60 per cent; red blood cells, 3,200,000; white blood cells, 17,000; polymorphonuclears, 80 per cent; lymphocytes, 8 per cent; monocytes 6 per cent; platelets, 350,000; lysis, 12 per cent; tourniquet test, negative; clotting time, ten minutes; bleeding time fifteen minutes; clot retraction, absent. Transfusion was effective, but vascular therapy was without avail.

DISTURBANCES IN VASCULAR FUNCTION

The bleeding problems of the vascular group are, strictly speaking, nonhemorrhagic diseases. The blood in each disease shows no abnormality in clotting function but capillary dysfunction. The vascular changes are produced in one of several ways: softening of cement substances binding the endothelial cells, injury of the living cells, destruction of elastic fibers and disturbance in innervation for normal contractility of the walls of the vessels. The hemorrhagic disturbances are spontaneous, single or multiple, but with little tendency toward continued bleeding. The bleeding in each of these diseases is better tolerated than in those of abnormal blood content. The transient injury to the capillaries becomes manifest in extravasations of blood, as in scurvy, Schönlein's and Henoch's diseases, on the one hand, and by blood combined with inflammatory exudations, as in severe infectious diseases and in chemical poisoning, on the other. Effective treatment of the heterogeneous group depends on the administration of substances to decrease capillary permeability immediately while the controlling factors are being corrected.

Avitaminosis.—Vitamin deficiency results in degeneration of the capillary endothelium. Scurvy is the classic example of the specific relation of vitamin C deficiency to the extravasation of blood under the periosteum and in the deep muscles, and into the skin and mucous membranes and around hair follicles. Infection accentuates vascular injury. Aschoff demonstrated separation of cement substances binding vascular endothelial cells. The blood-clotting function is normal, except for the positive tourniquet test, which is indicative of capillary injury. In severe cases there are changes in the bone marrow, with interference in the myeloid activity, causing a diminished platelet formation. But the initial vascular phenomena control the clinical picture of scurvy in children.

Deficiency in vitamin B_1 (or F) has likewise been demonstrated to injure the vascular endothelium to the extent of producing hemorrhagic manifestations. There is evidence that deficiency of this vitamin in the diet of the pregnant woman is one of the factors responsible for hemorrhagic disturbances in the new-born child involving vascular injury. Hemorrhagic manifestations definitely associated with avitaminosis have been observed in the course of marasmus and Herter's infantilism. The nutrition of the vascular endothelium evidently depends in part on vitamin adequacy,[9] the minutiae of nutrients, while blood content in clotting substance depends on the gross nutrients, protein and fat.

Allergic Purpura.—Recurring symptom complexes of the skin, joints or intestines reveal purpuric spots. Cutaneous eruptions with erythema, urticaria and angioneurotic edema as well as purpura constitute erythema multiforme. Mild arthritis with pain, tenderness and swelling of the joints of the lower extremities clustered with purpuric spots constitute Schonlein's purpura. Attacks of colic, with abdominal pain, tenderness and rigidity, purpuric spots over the skin and blood in the vomitus, urine and stools constitute Henoch's purpura. The blood-clotting function is normal but for the positive capillary resistance test. This heterogenous group of syndromes has a common allergic basis in that increased capillary permeability is suddenly produced by certain foods or bacterial toxins in allergic children.

Treatment involves clearing up of the infection and simultaneous elimination of the allergic offense. Intestinal disinfectants, colonic irrigations, belladonna suppositories, protein desensitization, ephedrine administration, salicylate medication and intravenous saline and calcium therapy are the effective procedures. Injection of foreign protein results in violent reactions; transfusions are unnecessary and splenectomy, of course, out of order.

E. M., a girl aged 5 years, the daughter of a physician, on presentation had purpuric spots over the lower extremities. There was great anxiety about threatened splenectomy. A year ago, the child had severe tonsillitis, with associated pain in the abdomen, knees and legs. After subsidence of the fever, tonsillectomy was performed on the basis of supposed rheumatic fever. After the operation purpuric extravasations and petechiae appeared over the legs. No such manifestations again appeared until this winter, when a similar syndrome recurred after each infection of the upper respiratory tract. Attacks of urticaria and ecchymoses alternated or appeared simultaneously. The child was admitted to the hospital for study as having a case of allergic purpura. Platelets numbered 385,000; the tourniquet test was positive, and the clotting and bleeding times normal. Both the father and the patient were allergic. Bacterial desensitization is in progress.

A. W., a girl aged 12 years, with similar symptomatology, was seen in consultation during an attack that simulated gastric ulcer. Hematemesis, abdominal pain and epigastric tenderness clouded the clinical picture. The blood picture and a roentgen series of the gastro-intestinal tract were negative. During convalescence deep intramuscular hemorrhages prolonged the pain and tenderness of the lower extremities.

Hemorrhagic Infectious Diseases.—Hemorrhagic symptoms predominate in infectious invasion. Vascular injury usually exceeds the disturbances in myeloid function, but the relative changes in each depend on the severity of the infection. I have observed as confirmation of vascular injury petechiae containing the organisms of meningococcemia, embolic abcesses with visceral hemorrhages in pneumococcemia, nosebleeds and even hemorrhagic sputum in epidemic influenza, thrombotic petechiae consisting of tuberculids, punctate hemorrhages in scarlet fever, bleeding of the mucous membranes in diphtheria, hemorrhages from the mucous membranes in congenital syphilis and purpura associated with the presence of endothelial cells in circulating blood of subacute bacterial endocarditis.

Capillary hemorrhages are not infrequent as consequences of vascular congestion in the course of chronic infections. Rheumatic heart disease induces epistaxis or congestion hemorrhages in the lower edematous extremities. Pertussis precipitates hemorrhages into the conjunctivae and eyelids as well as from the nose and bronchi. Uremia occasionally reveals terminal cerebral, retinal and intestinal hemorrhages rather than petechiae. The hemorrhagic symptoms in uremia parallel the severity of capillary damage from infection and not the degree of nitrogenous retention Increased venous pressure in normal circulatory systems is not a determining factor in these bleeding manifestations.

Arrest of bleeding in the course of infectious invasion may be brought about by therapeutic measures for decreasing capillary permeability. Elimination of infection is, of course, the primary concern, but the self-limited nature of infectious disease necessarily requires vascular medicaments. Clinically, calcium salts have been used in most hemorrhagic diseases for centuries, with favorable effect but based on erroneous interpretations. The calcium required in the clotting mechanism is rarely found wanting in amounts necessary for this process. Even the striking clinical entities involving hypocalcemia never reveal bleeding symptoms.

Table 8.—*Therapeutic Measures for the Arrest of Bleeding*

Procedure	Platelet Deficiency	Fibrinogen-Prothrombin Diminution	Vascular Disturbance
Local..	Coagulen, ultraviolet irradiation	Thromboplastin, meat juice	Styptysate
Oral. .. .	Viosterol	Cephalin, fibrinogen	Calcium salts
Nutritional .	Dietary fat (unsaturated lipids)	Dietary protein (gelatin, viscera)	Base forming foods
Intramuscular	Foreign protein	Blood serum	Pituitary parathormone
Intravenous...	Transfusion	Transfusion	10% calcium salts, 10% gelatin

Calcium therapy is indicated in abnormal bleeding resulting from vascular dysfunction. Its effect is specific in decreasing capillary permeability. The calcium salts administered have no bearing whatever on elevating the well buffered calcium content of the blood. Calcium therapy is best administered intravenously in a 10 per cent solution of calcium gluconate or calcium chloride, from 10 to 25 cc. injected very slowly. Oral administration is, of course, slower in its effect, but may well be supplemented in from 5 to 10 grain (0.33 to 0.65 Gm.) doses offered between feedings to prevent its precipitation into the intestinal tract and subsequent loss in the stools.

The administration of gelatin arrests bleeding by condensing platelets on the vascular bed. It may be injected intravenously in 10 per cent solution from 20 to 40 cc., or fed in 10 per cent solution either directly, sweetened and flavored with vanilla, mixed with milk or as a jelly, which may be kept on ice for two days.

Solution of pituitary is an effective vasoconstrictor in arresting bleeding. This mechanism is operative in vascular beds other than those of the female genital organs. The injection of 0.5 cc. of pituitary frequently suffices to arrest capillary oozing when due to vascular injury. The action is more prolonged than that of epinephrine hydrochloride. It is the vasopressor fraction of the posterior lobe that affects the vascular endothelium in the direction of increased blood coagulation.

Diet affects the hemorrhagic status of patients even in the course of severe infection. It tends to increase the blood clotting components to the extent of producing a thrombotic picture. And yet bleeding from mucous membranes may be present because of embolic phenomena associated with the vascular injury. Therefore, the dietary indicated is for reduction of the increased coagulability of blood. This is attained by fruits, vegetables and carbohydrates, with the exclusion of proteins and fats.

H. R., a boy aged 4 years, was admitted to the hospital with a history of convulsions associated with a severe infection of the upper respiratory tract. Hemorrhage appeared in the orbit and marked purpuric extravasations over the trunk and upper extremities. Facial weakness and complete right hemiplegia followed. Examination of the spinal fluid gave negative results. Examination of the blood showed: clotting and bleeding times, normal; tourniquet test, positive; platelets, 310,000; platelet lysis, 35 per cent, and blood clotting function, normal. An encephalitic infection was the cause of the purpura.

N. C., a boy aged 5 years, had recurrent severe epistaxis in the course of osteomyelitis with septicemia. The blood clotting function was five times normal, with platelets ranging around 1,300,000 per cubic centimeter, and yet vascular injury as a result of the infection was not compensated for by the thrombotic blood picture. On the other hand, I have seen neither hemorrhagic symptoms nor angina in B. S., a boy of 8, with lymphatic leukemia and a platelet count as low as 40,000. It is folly indeed ever to relate the hemorrhagic status to one factor alone.

SUMMARY

1. Hemorrhagic disturbances are syndromes associated with many diseases and produced by varied causes.

2. Clinical examination must be correlated with the blood picture in arriving at a diagnosis of hemorrhagic disease.

3. Methods are presented for the determination of the hemorrhagic status of a patient in terms of degree of function of the vascular endothelium and its blood content.

4. Hemorrhagic problems are rarely patterned according to the textbook, although a clotting component or a vascular alteration determines the controlling factor diagnostic of the disease.

5. Potential hemorrhagic disturbances reveal a low index of blood clotting function improved by a dietary high in protein and fat.

6. Potential hemorrhagic disease of the new-born may be prevented by the oral administration of gelatin solution and prenatally by a clotting dietary.

7. Diagnostic differentiation with appropriate therapy is given critically for problems of thrombocytopenic purpura.

8. Bleeding associated with diseases of the liver is interpreted on the basis of disturbed liver function.

9. Hemophilia, a clinical chimera for abnormal bleeding problems, can be definitely diagnosed and controlled therapeutically.

10. Abnormal bleeding resulting from vascular injury constitutes nonhemorrhagic disease characterized by normal blood clotting function.

11. Avitaminosis results in degeneration of the vascular endothelium observed in scurvy, marasmus and Herter's infantilism.

12. Allergic purpura, previously designated as erythema multiforme, is a symptom complex involving the skin, joints and intestines, Schönlein's purpura and Henoch's purpura, respectively.

13. Severe infections and chemical poisons are primarily toxic for capillaries, requiring vascular medicaments for arrest of bleeding.

14. Atypical hereditary hemorrhagic diseases involving deficiency in "clotting components" or in vascular endothelium still prevail without diagnostic characterizations.

15. A clinical classification of hemorrhagic diseases is offered, based on alterations in vascular endothelium or its blood content.

1060 Park Avenue.

ABSTRACT OF DISCUSSION

DR. HEYWORTH N. SANFORD, Chicago: When Dr. Kugelmass's work was first published, two years ago, it occurred to me that in the new-born a valuable medium had become available for the study of this problem. Here is an organism that has as yet not been influenced by external conditions. In using this method I obtained the values of fibrinogen, prothrombin and antithrombin on thirty-five new-born infants daily and was surprised to find that in every instance these values were high enough to cause an increase in the clotting index or, rather, to show that in all these cases there was every indication against the blood of the new-born clotting unless some external factor was brought into play. In an attempt to manipulate these clotting components to see whether clotting in the new-born could be increased or decreased, a number of things were tried. First, I attempted this by giving large doses of vitamin D in the form of viosterol and using ultraviolet rays. Dr. Kugelmass has stated that he was unable to find very much change in these elements, using vitamin D and ultraviolet rays. That is quite true. But if excessive doses of viosterol, as high as 60 drops a day, are used, and long exposures to ultraviolet rays, as long as ten minutes, one can by increasing the fibrinogen cause a slight increase in the bleeding time and coagulation time. I might say the increase in fibrinogen is compensated for by an increase of antithrombin, so in a few days the patient is worse off than he was before, and his blood will not clot as readily. In continuing the study, it occurred to me that possibly food elements had considerable to do with this. About six months before, I had begun a complement feeding in which two-thirds milk and one-third water and 6 per cent dextrose was given to infants as soon as they were born. If this had anything to do with the clotting components, obviously if protein and fat were withdrawn one would expect to find certain differences. Therefore, in a group of new-born infants, all feeding was withheld for the first five days of life, with the exception of 6 per cent dextrose ad libitum, and Ringer's solution. The children were all normal.

There was no loss of weight or any dehydration temperature The fibrinogen was decreased in all of these cases, so that the children were becoming essentially hemorrhagic I might say that in using this heavy protein and fat feeding as an early complement for the last two years, I have not had a single case of hemorrhagic disease on my service By manipulation of the fat and protein in the diet, it is possible to change the coagulation of the blood practically at will

Dr I Newton Kugelmass, New York *Dr Sanford confirmed strikingly my work on the dietary role in hemorrhagic* diseases, so far as it applies to the new-born This he has done even more effectively than I have been able to demonstrate in the heterogeneous *bleeding problems that have been* studied during the past five years The difficulty of obtaining blood from new-born infants has been compensated for by the clarity of results obtained at that period of life which is as yet uninfluenced by the varied factors that modify the hemorrhagic status of children It is gratifying that Dr Sanford found my index of clotting function applicable to the study of hemorrhagic disease So far as vitamin D is concerned in the clotting mechanism, I have not observed marked changes in the platelet count unless dietary fat had been considerably reduced for prolonged periods of time Fat intake, particularly in unsaturated lipids, appears to parallel the level of blood platelets, but the vitamin D content is not as directly related Its effect is more to mobilize the available calcium for decreasing capillary permeability than to any other phase of the clotting process I have not had occasion to study the effect of large doses of vitamin D or ultraviolet irradiation on the clotting mechanism, as has Dr Sanford I have concentrated more on manifest bleeding problems to determine to what extent they can be influenced by different therapeutic procedures as measured by the index of clotting function

SICKLE CELL ANEMIA

W WILLIS ANDERSON, M D
AND
ROBERT L WARE, M D
ATLANTA, GA

Twenty-two years have elapsed since Herrick[1] first described a case of sickle cell anemia During this period, sixty odd cases of the condition have been reported in detail, and mention has been made in the literature of more than a hundred others Considerable experimental work has been done in investigation of the cause and nature of sickle cell anemia, with results that sometimes conflict

ETIOLOGY AND INCIDENCE

Sickle cell anemia is a disease of young people The average age in the reported cases is 13 years Only five cases have been reported in patients over 30, though one case has been reported at 62[2] The youngest patient whose case was reported was 7 months old[3] The low age incidence is explained by the fact that these patients have a decreased resistance to disease, and usually succumb early to respiratory or other infections

Males are affected more than females, in a ratio of almost 2:1 in the reported cases

The disease affects the colored race primarily, and until recently it was believed that it occurred only in Negroes Cases were reported in an Arab[4] and a Cuban,[5] in neither of whom the possibility of Negro blood was excluded Castana[6] reported a case in an Italian, and Cooley and Lee[7] described a typical case in a Greek child in whom the possibility of Negro blood was practically excluded Recently, Sights and Simon[8] have added to the literature a well marked case in a man of Scotch-Irish blood These cases definitely establish the occurrence of sickle cell anemia outside of the colored race, although it is among Negroes that the disease is chiefly found

All except two cases have been reported from the United States In this country the disease is distributed roughly according to the proportion of Negro population, the greatest number of cases being found in the Southern states

The disease shows a definite familial tendency. In a number of cases in which blood from other members of the patient's family was examined, sickle cells were found Huck[9] demonstrated this feature quite decisively in a study of two families through three generations He concluded that the condition is transmitted according to the mendelian law as a dominant trait.

PATHOLOGY[10]

The pathology of sickle cell anemia is limited to the spleen, liver and bone marrow; the most characteristic picture is found in the spleen The spleen varies greatly in size, cases having been reported in which it weighed 24[11] Gm and 621[12] Gm In general, it may be said that the spleen enlarges rapidly during infancy and gradually becomes atrophic after the child reaches the ages from 4 to 6 years The average age of patients with enlarged spleen is 5 years The largest spleens are usually found in the youngest patients, though there are exceptions to this rule.

The splenic capsule is thickened and often rough The cut surface of the organ is darker than usual and

[12] Landon and Lyman (footnote 10 *i*)

frequently shows light red or yellow spots which prove to be infarcts On microscopic examination the characteristic picture is seen The malpighian bodies are greatly diminished in size, are fibrotic and may not show germinal centers The sinuses about the corpuscles are dilated and distended with red cells so that the corpuscles appear to be swimming in a pool of blood Rice[13] believes that this is a congenital malformation of the splenic sinuses and suggests such a cause for the disease The pulp is usually invaded by red cells and may be either swollen or atrophic and fibrotic, according to the size of the spleen Large numbers of sickle cells are seen

The liver is practically always enlarged The parenchyma shows moderate albuminous or fatty degeneration, and the sinusoids are dilated Quantities of sickle cells are present, though not so many as in the spleen Some observers[14] have noted phagocytosis of sickle cells by the Kupffer cells The cells lining the sinusoids may show hemosiderin pigment

The long bones show hyperplasia of the marrow The inner half of the cortex has been found honeycombed by marrow interspersed with bony trabeculations An unusual number of nucleated red cells are found, nucleated sickle cells are frequently seen In general, there is evidence of hyperactivity of the bone marrow

The lymph glands are generally enlarged, but microscopic examination does not reveal any characteristic changes The ulcers of the legs show nothing of special interest

MECHANISM OF SICKLING

In view of the fact that both nucleated and reticulated sickle cells have been reported by several observers, it appears fairly certain that the transition of the red cells to the sickle shape occurs early in their development The factors that influence this transition have been the subject of a great deal of investigation, which has led to varying conclusions

Hahn and Gillespie[15] were able to produce sickling immediately by saturating a suspension of cells from a patient with sickle cell anemia with carbon dioxide, and, to reverse the process, to recover round cells by saturation with oxygen This led to the theory of anoxemia as a cause of sickling

Scriver and Waugh[16] applied this theory to a living patient They effected venous stasis in an arm by a tight Esmarch bandage and found a decreased percentage (23 per cent) of oxygen in the blood and saw sickling of 95 per cent of the cells Under conditions of optimum circulation, produced by massage and hot water, they found an increased oxygen concentration (62 5 per cent) and only 5 per cent sickle cells This experiment in vivo correlates perfectly with Hahn and Gillespie's experiment in vitro

On the other hand, in a study of seventy-seven tuberculous patients, three of whom showed the sickle cell trait and one active sickle cell anemia, Dolgopol and Stitt[17] failed to find any relationship between the degree of anoxemia and the severity of the disease Moreover, Graham and McCarty,[18] under anaerobic conditions, withdrew blood from the right auricle of the heart twenty-seven hours after death, when anoxemia should have been extreme, and found no more sickle cells than had been present during life

A number of other theories[19] have been advanced, but the actual mechanism is still in question.

SYMPTOMATOLOGY

The history elicited from a patient with sickle cell anemia, while suggestive, is by no means diagnostic The patient is usually presented for examination because of weakness, easy fatigability, shortness of breath or "general run-down condition" If one of the acute exacerbations characteristic of the disease is in progress, there may be severe abdominal pain with nausea and vomiting, the syndrome may suggest acute rheumatic fever, with joint pains, a temperature from 101 to 103 F and leukocytosis In the absence of these acute manifestations of the disease, a history of one or more such attacks can usually be obtained The informant will explain that the patient has been weak and sickly all of his life, and that the common diseases of childhood were unusually severe There will be a history of frequent colds, tonsillitis and possibly pneumonia or tuberculosis As a matter of fact, the disease is often discovered while the patient is being treated for some respiratory infection

On physical examination, the patient is found to be rather small for his age and undernourished Anemic pallor, of course, is obscured by the skin of the Negro, but it is quite evident in the conjunctivae and oral mucous membranes of these patients The sclerae are almost always found to be jaundiced or to have a pale greenish appearance

The tonsils are usually diseased, and there is a more or less generalized enlargement of the lymph glands This adenopathy is most evident in the cervical and axillary lymph nodes which drain the troublesome respiratory tract

Cardiac enlargement is present in about one half of the cases Sickle cell anemia is sometimes associated with rheumatic heart disease, but by no means often enough to explain the cardiac hypertrophy on that basis Analysis of the reported cases shows that, more often than not, the rheumatoid symptoms and enlarged heart occur independently of each other In most instances there is a soft systolic murmur at the apex, not transmitted, which is explained by the anemia

Examination of the lungs often shows some degree of congestion This is considered secondary to the disease, but it is mentioned to emphasize the importance of pulmonary complications

The abdomen may be tender during an exacerbation but the pain and tenderness are seldom localized The liver is enlarged in about one half of the cases, the edge being felt two or three fingerbreadths below the costal margin The spleen is usually enlarged in patients under 4 years of age, but it is seldom palpable in patients older than 7 years In babies it is often enormously hypertrophied, reaching the iliac crest, and may be quite tender An enlarged spleen diminishes in size during a remission of the acute symptoms

In some of the patients past the age of puberty, evidence of retarded sexual development is seen. Scanty or absent pubic and axillary hair may be noted, and cryptorchidism is occasionally found. Patients who showed these findings were otherwise generally underdeveloped.

Chronic ulcers of the legs are almost universal among the adolescent and adult patients, but seldom occur in the younger ones. Only two cases of ulcer have been reported in patients under 16 years, while practically all patients of 16 or over have shown either active ulcers or scars. The ulcers resemble those of syphilis, occurring on the shins and ankles, and having a punched-out appearance.

Laboratory examination of the blood shows marked anemia, an average red cell count around 2,500,000 and a corresponding hemoglobin from 40 to 50 per cent. In severe cases the count drops below 1,000,000, and the hemoglobin may be from 10 to 12 per cent. The white blood count is usually from 11,000 to 12,000, even in the absence of infection; the differential count shows an increase in neutrophils. Varying degrees of anisocytosis and poikilocytosis are noted in the stained smear, and infrequent sickle cells are seen. Nucleated red cells are found, and there is an increase in reticulocytes. The red cells show an increase in resistance to hemolysis. The van den Bergh test is occasionally positive in the direct phase and almost always positive in the indirect phase. Urobilinuria is noted in many cases.

As was mentioned, sickle cells are seen but infrequently on stained slides. The characteristic and diagnostic shape of the cells is brought out by sealing a drop of blood between a slide and a thin cover slip. Petrolatum was first used,[20] but later cedar immersion oil was found to be more convenient for sealing the cover slip. The preparation is incubated at room temperature for twenty-four hours. Sickle cells appear after from one to four hours and become increasingly numerous, reaching from 60 to 100 per cent by the end of twenty-four hours. The cells are elongated and crescentic, with threadlike processes extending from the tips. If the preparation is preserved for from four to six days, the cells are seen to have reverted to the normal round shape.

DIAGNOSIS

The diagnosis is based on the characteristic appearance of the red cells, the presence of anemia and the evidence of jaundice. There are only two conditions that need to be considered in the differential diagnosis.

The sickle cell trait exists in about 7 per cent of normal healthy Negroes. Blood from these subjects shows sickle cells in the same manner as that from patients with sickle cell anemia, but there is no anemia or any other abnormal characteristic. The sickle cell trait produces no symptoms and is not incompatible with long life; it has never been known to develop into sickle cell anemia.

There is another condition, which has been called Dresbach's syndrome,[21] in which elliptic cells roughly resembling sickle cells are found in the blood of normal subjects. No symptoms are produced by this condition. The number of abnormal cells is not increased in a sealed preparation, thereby differing from sickle cell anemia.

The simplicity and conclusiveness of the sealed preparation as a method of diagnosis makes it advisable for use. Every Negro with anemia, jaundice or other suggestive signs should be studied for sickle cell anemia, and in white people the disease should be considered as a possible diagnosis in cases of unexplained anemia.

TREATMENT

As yet, no satisfactory method of treatment has been found. General measures for building up the body resistance are in order, and stimulants to the blood-forming organs have value. Some patients have been relieved of all symptoms by liver diet, while others have not been benefited. Transfusions have only a temporary effect. Splenectomy has been advocated, and several such operations have been performed. The operation was usually followed by a period of improvement, but in half of the cases the anemia recurred after a few months. The removal of an enlarged spleen appears to be more beneficial than the removal of a small spleen.

Frequency of Occurrence of Signs and Symptoms of Sickle Cell Anemia[22]

	Per Cent
Symptoms:	
Abdominal pain	55
Joint pain	51
Weakness	41
Vomiting	28
Physical Signs:	
Greenish-yellow sclera	78
Heart murmur	75
Adenopathy	55
Enlarged liver	53
Enlarged heart	48
Pathologic changes in lung	39
Ulcer or scar of leg	39
Fever	33
Enlarged spleen	30
Infantile genitalia	17
Laboratory Results:	
Fragility decreased (68 per cent of the 35 cases in which fragility was determined)	68
Nucleated red cells present	57
Indirect van den Bergh positive	55
Urobilinuria	42
Direct van den Bergh positive	12

PROGNOSIS

Between the acute phases of the disease are periods of one to two years during which the patient feels fairly well and is able to carry on the usual routine of life, though he is seldom able to perform heavy work.

The patient may survive a number of acute exacerbations, but owing to his decreased resistance, he is a prey to the various infectious diseases, and usually succumbs to one of these. Few patients live beyond the age of 35 years.

ABSTRACT OF DISCUSSION

Dr. George S. Graham, Birmingham, Ala.: There has been a good deal of difficulty in establishing a satisfactory definition of the disease "sickle cell anemia." The difficulty arises particularly from the fact that too many normal people exhibit the peculiar deformability of the red cells that has given the disease its name. While from 7 to 8 per cent of all Negroes show this erythrocytic abnormality, only an occasional individual suffers an associated anemia of disabling grade. Sydenstricker recognized the problem and suggested that the disease may exist in a latent as contrasted with an active form. Similarly, the deformity might be considered merely as an indication of some peculiarity of the red cell or of the blood as a whole, while the term "sickle cell anemia" might be reserved for those cases that show definite evidence of disease. Given the peculiar red cell quality as an inherited trait, it is probable that in any particular individual the subsequent course of evidents will depend on accessory factors that are not as yet understood. The red cells as seen in the centrifuge tube or in fresh preparations under the microscope appear soft and pliable and have a viscous, sticky quality. This and other considerations have led to the belief that the deformity is purely a physical phenomenon rather than one dependent on particular conditions of hemoglobin combination, as has been hypothecated by others. I am in agreement with Drs. Anderson and Ware in finding that the cells exhibit an increased resistance to hypotonic salt solutions. However, there can be no doubt that within the body they suffer an accelerated rate of hemolysis. The evidence for this is found quite regularly in the active phases of the disease and is demonstrable post mortem even in the organs of nonanemic individuals, in whom deposits of hemosiderin are found in the renal epithelium and in the reticulo-endothelial cells, particularly those of the liver and lymph nodes. Differential diagnosis is important. The abdominal pain, leukocytosis and fever typical of the crises that are seen in anemic subjects may suggest acute abdominal disease. The associated jaundice may simulate that of cholecystitis. I have seen two cases in which the acute abdominal symptoms had led to the removal of normal appendixes. Here is perhaps the most practical aspect of the whole problem, and it should be emphasized that in dealing with the Negro patient one should always keep the disease in mind.

Dr. Thomas B. Cooley, Detroit: This is a disease of childhood. The earliest reports led one to think that it was about as frequent and as important in adults as in children. Obviously, from further study, that is not the case. I have an idea of the reason for this somewhat different from the one given by the authors. Drs. Anderson and Ware think that most of the patients die before they reach adult life. I have not watched my patients to adult life, but I have the impression that there is a tendency to improvement—toward what may be called a "compensated" state, such as one sees in hemolytic icterus. How correct that impression is I am not sure, but I have a number of patients who are having less trouble now than they did; fewer hemolytic crises and few abdominal and joint pains. So I am inclined to believe that there may be a natural tendency to improve. None of the patients that I have lost have died of actual effects of sickle cell anemia. One died of tuberculosis, another of endocarditis and a third of a surgical accident. The others, so far as I know, are all living. I want to call attention again to the general similarity of this disease to congenital hemolytic icterus. With regard to the question of latency, those who are familiar with Gänsslen's studies of hemolytic icterus will remember that a large number of the persons he investigated in affected families showed one or more of the recognized characteristics without ever having the hemolytic anemia itself. It seems to me that there is a close analogy there with sickle cell anemia. There are three main symptoms in sickle cell anemia which call for treatment, if one can do anything to relieve them. The first is the hemolytic crises, which occur, as a rule, in connection with acute infections, and in the course of which the blood is likely to drop to a pretty low level. Temporarily, the patients are easily handled by transfusion, and that is the obvious immediate treatment. As for prevention, the feeding of iron or liver does no good. Of course, the removal of probable sources of infection, such as diseased tonsils, and the treatment of infected sinuses may help, but on the whole I have found nothing definitely protective in any of these things. I do think that I have seen a lessening of the hemolytic crises and more of a tendency to reach a compensated state after splenectomy. From this point of view the operation seems worth while. The other two things of main importance in the symptomatology are the abdominal and joint crises. The abdominal pains seem to be due to splenic thrombosis. If the spleen is removed shortly after one of these crises, it will be found to show infarcts due to thrombosis, which may be very large. I don't think the joint pains are of the arthritic type. I should like to be able to relate them to the thrombotic process. They are not relieved at all by antiarthritic measures. They are liable to occur in the patients who have the splenic crises, and often at about the same time. In the two cases in which I have tried it, they seemed to be relieved as definitely by splenectomy as were the abdominal pains.

THE INCIDENCE OF CARCINOMA IN CERTAIN CHRONIC ULCERATING LESIONS OF THE STOMACH

GEORGE W. HOLMES, M.D.
AND
AUBREY O. HAMPTON, M.D.
BOSTON

The successful treatment of carcinoma by any method available at the present time seems to depend more on early diagnosis than on any other single factor; carcinoma of the stomach is no exception to this general rule. Through the efforts of the Society for the Control of Cancer and the medical profession in general, the public is being educated to the necessity of early diagnosis and treatment. Patients are appearing at clinics with a much earlier stage of the disease than formerly, and the responsibility for correct diagnosis is becoming increasingly greater as well as more difficult.

Among the problems that arise, perhaps one of the most difficult is the determination of the benign or malignant character of chronic gastric ulcerations. While it is true that the diagnosis is comparatively easy either by the roentgen rays or by examination on the operating table in well developed cases, it is also true that in the earlier and less well defined cases the differentiation is often impossible by either method. Numerous cases are cited in which mistakes have been made by both surgeons and pathologists, and the correct diagnoses were not established until serial sections and microscopic studies of the ulcer-bearing areas had been carried out. In these early cases the clinical history may be of little value in the differential diagnosis. Analysis of the gastric contents may be the same in either case. A response to ulcer treatment may also be misleading. Patients with early malignant ulcers often do well for a time on an ulcer regimen, and the lesion itself may appear to get smaller as shown by roentgen studies. The time lost in carrying out such a procedure is also a definite risk if the lesion proves to be malignant. In an attempt to solve this problem it occurred to one of us (A. O. H.) that the location of

---

From the Massachusetts General Hospital,

Read before the Section on Gastro Enterology and Proctology at the Eighty-Third Annual Session of the American Medical Association, New Orleans, May 12, 1932.

the ulcer-bearing area might be of considerable importance in the differential diagnosis.

In general, authors of textbooks and the medical literature pass over this subject with the statement that benign gastric ulcers are chiefly found in the lower third, along the lesser curvature, and that a large percentage of these ulcers are within the duodenum and pyloric valve. A few pathologists and roentgenologists, however, have studied this subject more carefully and have attempted to localize the areas within the stomach in which benign ulcers or carcinomas are more likely to be found.

Orator[1] studied 330 cases of gastric ulcers obtained from Eiselberg's clinic; his conclusions are based on the gross appearance and the histologic examination. Of the total of 330 ulcers, 300 were in the middle third of the stomach near the lesser curvature, and 30 were in the prepyloric region. When studied histologically, 6 of the 300 ulcers on the lesser curvature and 15 of the prepyloric ulcers showed evidence of malignant degeneration; 15 others were questionable. Orator does not state clearly the position of this questionable group. There were no benign ulcers on the greater curvature or in the fundus of the stomach.

Lehmann examined the stomach and duodenum in 1,000 cases at autopsy for signs of active or healed ulcers. Ulcers, or the scars from ulcers, were found in 202 cases. In the stomach the relation of scar to active ulcers was as 9 to 1; the number of active ulcerations increased as the pylorus was approached. By far the greater number of scars were located toward the cardiac end of the stomach. Seventy-one per cent of active ulcers were observed in the region of the lesser curvature of the stomach. Not a single instance of benign ulcer was observed on the greater curvature.

Haudek,[2] reviewing his experience of many years in the roentgen diagnosis of gastric lesions, recognized the difficulty in distinguishing between benign and malignant lesions in the prepyloric region. The prepyloric region, he stated, is the most frequent site of cancer; about 80 per cent of carcinomas start there. Ulcers are certainly less commonly found in this area, occurring in about the proportion of 1 to 10 as compared with ulcers in the pars media. He further stated that a considerable percentage of these ulcers degenerate and become malignant; about one third of the prepyloric ulcers undergo this change, while only 3 per cent of the ulcers of the pars media do so. He concluded that the difficulty in differential diagnosis with the tendency to malignant degeneration is sufficient reason for recommending operation in all prepyloric ulcerations.

Sproull,[3] in a careful review of the literature, was able to find only 10 proved cases of benign chronic ulcerations on the greater curvature. More than half of the cases reported either were not proved histologically, or on examination were found to be malignant. He concluded that no lesion of the greater curvature should be treated by medical measures, no matter how small the lesion or how closely the clinical and roentgen findings may simulate benign ulcer, for the chance that it is not benign is so great that one will be almost surely missing the opportunity to remove an early cancer.

Dresser[4] quoted Lehmann and referred to the frequency with which benign ulcer occurs on the lesser curvature of the stomach.

Camp,[5] in a summary of the facts concerning prepyloric ulcer obtained from the literature and from the material at the Mayo Clinic, stated that it is apparent that the roentgenologic simulants of this lesion are numerous and far more common than prepyloric ulcer itself, and he advised withholding a diagnosis unless an ulcer niche can be demonstrated without question.

Stone and Ruggles[6] have also studied the cause of deformity of the prepyloric region and have noted the frequency with which these lesions are found to be malignant. They reported 1 case of proved benign prepyloric ulcer.

In general, it may be stated that those authors who have studied the location of benign and malignant gastric ulcerations agree that there are definite ulcer-bearing areas and that these areas are along the middle third of the lesser curvature, at the pyloric valve and in the duodenal bulb. There also seems to be general agreement that carcinoma may occur anywhere in the stomach, that it is most frequently found in the prepyloric region, and that it rarely involves the duodenal bulb. In the early diagnosis of a gastric carcinoma the prepyloric region is particularly important since a lesion occurring in this area gives symptoms early, and these patients are likely to report for observation at a time when a cure is possible. Carcinomatous lesions occurring in other parts of the stomach may be symptomless until the lesion is well developed. The operative procedure is also simpler when the lesion occurs near the pylorus than in other parts of the stomach. The early correct diagnosis of these prepyloric lesions is, therefore, of special importance.

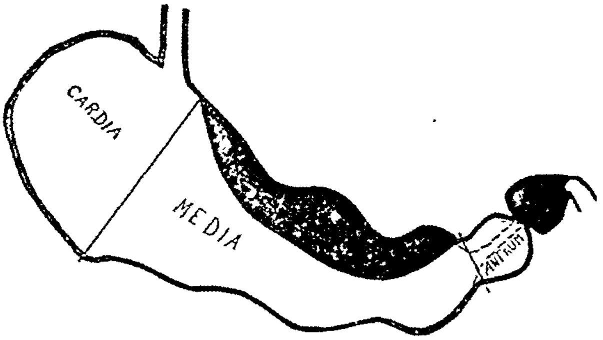

Diagram of the stomach, showing the anatomic divisions we have selected and the areas in which benign ulcers usually occur. Prepyloric ulcers as discussed in this paper occur within the antrum and do not involve the pyloric ring. Malignant ulcerations may occur anywhere in the stomach. The shaded areas indicate the position of benign ulcerations.

Before taking up the discussion of our material it is perhaps well to state definitely what we understand by the term "prepyloric region." As we understand it and as it is referred to in this paper, it is that portion of the stomach which forms the pyloric antrum and which, as the peristaltic waves pass over the stomach, forms a canal about 1 inch (2.5 cm.) in length just to the gastric side of the pylorus (see the accompanying figure).

The material we wish to present is based on a study of the records of the Massachusetts General Hospital during the past ten years and includes the combined roentgen, surgical and pathologic reports. It is rather disappointing that of this large amount of material only 128 records of benign gastric ulcerations were obtained in which all of the data were complete. It is only during the last three years that sufficient attention has been given to the localization of ulcerating lesions. Of these 128 benign gastric ulcerations, 83 were in the media close to the lesser curvature, 28 at the pylorus, "6 near the pylorus" and 2 in the prepyloric region; in 9 cases the location was in doubt. (table 1).

Table 1.—*Location of Ulcer of Stomach (Roentgen, Surgical and Pathologic)*

	Number	Per Cent
Location (?)	9	8.0
Pylorus	28	21 9
Near pylorus	6	4.6
Prepyloric	2	1.5
Media	83	74 0
Total	128	100

We have also studied the material for the years 1928 and 1929, based on roentgen examination alone. In these two years there were 128 benign gastric ulcerations and 121 gastric carcinomas. The location is as follows (table 2): Of the ulcers, 39 occurred in the pylorus, 6 in the prepyloric region, 80 in the midportion of the stomach and 3 in the cardiac region. Of the carcinomas, 75 occurred in the prepyloric and pyloric regions, 7 in the midportion of the stomach and 21 in the cardia; 8 were classified as diffuse. The relative proportion of benign to malignant prepyloric ulcerations was approximately 1 to 12. In the first group studied there were 8 cases each of which at operation showed a lesion near the pylorus in the prepyloric region which was diagnosed at operation as a benign ulceration and in which a gastro-enterostomy was done. Follow-up of these cases has shown that the diagnosis was incorrect in every case, the correct diagnosis being carcinoma (table 3).

Table 2.—*Location of Ulcer and Carcinoma; Roentgen Diagnosis (1928 and 1929)* *

	Ulcer	Carcinoma
Pyloric end (pylorus)	39	75
(prepyloric)	6	
Media	80	17
Cardia	3(?)	21
Diffuse	0	8
Total	128	121

* Relative proportion of prepyloric ulcer to carcinoma approximately 1 to 12.

SUMMARY

From a study of the literature and of our own cases we believe that it is fair to state that any chronic, indurated, ulcerating lesion occurring in the pyloric antrum within 1 inch of the pylorus, but without involving the pylorus, should be considered malignant until proved to be otherwise, and that proof of the absence of malignancy in such lesions is obtained only by serial section and careful microscopic examination. It is not safe to interpret such lesions as benign from roentgen examination alone or from observation on the operating table. Given a case presenting such a lesion in the prepyloric area, it is probably safer and wiser to treat the lesion by wide surgical removal than by medical or palliative treatment. The same is true of all chronic, indurated, ulcerating lesions occurring on the greater curvature and probably with most lesions occurring in the cardiac end of the stomach. The benign, chronic, indurated, peptic ulcer occurs on the lesser curvature above the antrum or in the region of the pyloric valve. Accurate localization of these lesions is of the greatest importance, but is sometimes difficult; foreshortening of the shadow of the stomach on the x-ray film may make the niche of the ulcer appear closer to the pyloric opening than it actually is. Careful fluoroscopic observation or films taken at various angles should obviate this error. Large ulcers occurring low on the lesser curvature may extend into the region of the antrum; similar ulcers arising in the region of the pyloric valve may extend into the stomach. They should not be classified as prepyloric ulcers.

Table 3.—*The Roentgen, Operative and Follow-Up Diagnosis in Eight Selected Cases of Prepyloric Ulcer*

Hospital Number	Roentgen Findings	Operative Findings	Final Diagnosis
283365	Gastric ulcer at the prepylorus (?); malignancy	Gastric ulcer on the lesser curvature 3 cm. above the pylorus (1927)	Tumor involving the pyloric end (1929), adenocarcinoma, removed; operative and pathologic diagnosis
273408	Obstruction at the outlet; probably malignant	Ulcer on the gastric side of pylorus (1925)	Operative findings, 1929: carcinoma, inoperable
272829	Obstruction at the outlet of the stomach	Thickening exactly at pylorus with ulcer above it (1925)	Roentgen and clinical findings, obvious carcinoma; patient died in January, 1927
262864	Obstruction at the pylorus	Lesion on the lesser curvature which ended abruptly at the pylorus; old callus ulcer (1924)	No operation; definite carcinoma; roentgen and clinical findings
481562	Obstruction at the pylorus, probably ulcer	Indurated lesion near the pylorus (1922)	Carcinoma lower third, 1923; adenocarcinoma· operative and pathologic findings
461562	Ulcer near the pylorus	Benign ulcer (1926)	Mass head of pancreas and large ulcer just above pylorus; malignant condition seemed certain (1927); operation
253001	Obstruction at the pylorus, probably ulcer	Ulcer above the pylorus (1921)	Enlarged liver, jaundice; roentgen diagnosis: carcinoma of the stomach (1922)
250411	None	Gastric ulcer (1920)	Palpable mass, obvious carcinoma (1922)

In this presentation we have purposely avoided a discussion of the various roentgen findings which help to differentiate benign from malignant ulcerations. other than position. They are all important, and all facts, including those obtained from the history and physical examination, should be considered in the final diagnosis.

ABSTRACT OF DISCUSSION

Dr. John D. Camp, Rochester, Minn.: It has been repeated here several times today that the roentgenologic distinction between gastric ulcer and carcinoma in most instances is quite easily accomplished; I think all will agree that this is probably true. Efforts are continually being made to improve the technic so as to diagnose operable malignant lesions of the stomach earlier, but in early cases differential diagnosis is more difficult and it is in this group that the information which the authors have presented will be found of considerable help. I should like to speak particularly of the lesions in the of the stomach to which the authors have referred. When one considers these, one finds among them 66 per cent of all gastric cancers, 69 per cent of all benign neoplasms of the stomach, and only 10 per cent of benign gastric ulcers. Since benign gastric ulcers in the antrum are comparatively rare, one must agree with the authors that a chronic ulcerating lesion in this region should be considered malignant until proved otherwise. The antrum is a favorite site of spasm referred from a gastric ulcer situated higher up on the lesser curvature or elsewhere in the stomach, and too frequently the spasm produces a rather marked six hour gastric retention, which may obscure the fundamental lesion and lead one to think one is dealing with a definite obstructing pyloric lesion. Early malignancy in the antrum may be obscured by the resultant stasis of barium, secretion and food remnants. Even when a pyloric lesion seems certain, the accuracy of the roentgenologic examination can be considerably enhanced if, in cases presenting obstruction, lavage is done before the roentgenoscopic examination. The differentiation between gastric ulcer and cancer cannot be accomplished in all cases. We must remember that as roentgenologists we are dependent solely on what we can see and when more than one disease may produce grossly the same pathologic picture, the decision must be left to the clinician, the surgeon and the pathologist.

Dr. Frank Smithies, Chicago: I am rather surprised at the statement that the literature contains very little reference to the location of gastric ulcer with respect to gastric cancer. While I thoroughly agree with the authors in their general conclusions, I wonder how they came to overlook the careful tabulations which the late Dr. A. J. Ochsner and I placed in our book "Cancer of the Stomach."

Dr. Martin E. Rehfuss, Philadelphia: As I see it, the question of peptic ulcer involves three factors. The first factor I would call an x factor because it is an unknown one. The second is the question of acid and pepsin, not acid alone, but pepsin. The third is a neuromuscular mechanism concerning which relatively little is known but of which a great deal is beginning to be learned. Dr. Cole gave as beautiful an elucidation of the question of gastric ulcer as I know of and he made a statement which we as clinicians can absolutely subscribe to and that is that gastric ulcer disappears with great rapidity. There has been a strong tendency to pass over today the distinction between gastric and duodenal ulcer. I have seen gastric ulcer on the lesser curvature and on the posterior wall disappear in two weeks, but I have seen it recur in a year on a number of occasions; therefore to assume that it is latent and disappears after treatment is a serious matter. There are three people I knew who paid the penalty for this assumption. Duodenal ulcer is an altogether different story. It is a disease which in the first hundred cases of my associates and me showed about 78 per cent of high acid figures. Moynihan reported 72 per cent of high acid in this group. Duodenal ulcer occurs in a little thin walled cap in 95 per cent of the cases, and the danger of duodenal ulcer is obviously greater from the standpoint of perforation. As to the etiology, one point that was not brought forward was infection. I think that is important because of the seasonal incidence and the studies of Duval; and the exacerbations of the disease suggest that; nevertheless, there are many points in the x factor, toxemia, allergy, heredity, and all those things that make an ulcer possible. With regard to the acid stage I disagree with Dr. Cole. I will look at his beautiful lantern slides and accept them. I will look at the elucidation of the pathologic changes in ulcer. I have never seen anything better; but he must present the figures on acid before I will accept that statement. I spent seventeen years studying the acidity of the stomach and I know that human beings belong in groups. One group presents a rather high acidity and, barring accidents and influenza and typhoid and age, they maintain that type of acidity throughout the greater part of their lives. I have records which go over fifteen years of gastric analyses that were made. Therefore I say that this acid factor is and must be a factor in the evolution of ulcer, because all the concrete testimony, surgical and medical, shows that it plays a rôle. This is one point the surgeon is fighting. He measures his effect not only by disappearance of ulcer but also by the control of acidity, and he gets the marginal type when the secretory mechanism is not controlled. I believe what Dr. Cole has said about gastric ulcer. If the patients are put to bed on a proper dietary, the big craters will disappear. Nevertheless I insist on roentgen control.

Dr. Lewis Gregory Cole, New York: I almost always agree with Dr. Holmes in problems of general roentgenologic diagnosis and roentgenologic therapeutics, but in gastro-intestinal diagnosis, in which our technic is radically different, our interpretation of the observations, and particularly our application of these observations to the many problems in gastro-enterology, often are at variance, and this presentation is no exception. The authors conveyed the idea that organic ulcerative lesions of the pylorus were malignant and that organic lesions of the lesser curvature above the sulcus were benign and they emphasized this by a schematic drawing of the stomach. The lesser curvature between the sulcus and the esophagus and the entire cap was filled in with black and the pyloric region on both the lesser and greater curvatures was white. I fear that they led the audience to believe that lesions occurring in the white region should be considered malignant and those lesions that occur in the black region should be regarded as nonmalignant. The cap is never the site of malignant tumors and is therefore eliminated from controversy. I feel that gastro-enterologists throughout the country and some roentgenologists with less experience than Drs. Holmes and Hampton will apply this schematic drawing to the solution of the problem of malignant conditions of the stomach. I fear that those less experienced in roentgenology will attempt to apply the schematic sketch of the stomach to the solution of the cancer problem. In my opinion if this statement and sketch were universally accepted as a prime factor in the differential diagnosis of malignant tumors of the stomach it would set back the science of roentgenologic diagnosis of gastro-intestinal lesions by nearly two decades, in fact almost to the period when reports read "There is a filling defect of the stomach which can be proved malignant or nonmalignant only by surgical exploration." In fact, I think it would be worse than this because those inexperienced in interpretation may derive a sense of false security of nonmalignancy in lesions along the lesser curvature and, still worse, be led to innumerable partial gastrectomies for nonmalignant lesions that would heal in a short time under proper medical treatment. If this schematic drawing were accepted I dread to think of the mortality of surgical procedures based on such roentgenologic evidence. The fatalities as a result of operative intervention in nonmalignant pyloric lesions would far exceed the five or even three year cures of gastric ulcer that might result from partial gastrectomy. Moreover, if adequate roentgenologic changes of the pyloric region are intensively studied, the differentiation between malignant and nonmalignant lesions of this region can be made in the vast majority of cases based on a single complete serial examination. In the few cases in which this differential diagnosis cannot be made from a single examination, a subsequent examination in two or three weeks will almost certainly give a differential diagnosis between a benign and a malignant lesion. The benign lesion will improve on rest in bed and the other is less likely to. I am certain that, in my experience, for every malignant organic lesion I could show a slide of a nonmalignant organic ulcerative lesion in the region which the authors have designated as the white area in which only malignant growths occur. I present a series of slides as controverting the fact that ulcerative organic lesions of the pylorus should be considered malignant until proved otherwise by surgical exploration.

Dr. George W. Holmes, Boston: What Dr. Cole said requires some restatement of my position. I don't agree with him that the surgical results are so bad; perhaps the Boston surgeons are more conservative; I don't feel as he does toward the surgeon. The paper that Dr. Hampton and I have presented has as its object the prevention of just such a situation as Dr. Cole has brought up—the case that he has cited. I don't wish to give the impression that this is the only way of finding out whether a patient has a benign or malignant ulcer, but it is one way of clearing up just such a situation. As to the slides Dr. Cole has shown, we have never stated that benign ulcers did not occur in the prepyloric region, and in the vast material which Dr. Cole has available he can no doubt find some that are benign, but they are not common If he will take all the cases he sees in a year and compare the percentage of cases presenting benign ulcer in the prepyloric area with those presenting benign ulcerations on the lesser curvature or in the pyloric region, I feel sure he will agree with us I do not agree with him on all the slides he has shown A good many of them were not prepyloric ulcers as I define them Some were, but in these he did not state whether or not a pathologic diagnosis was made, or the number of sections taken I will not accept the pathologist's report made from a single section in these cases

RECENT OBSERVATIONS IN SERUM DISEASE

LUKE W HUNT, M D
CHICAGO

It was thought that it might be profitable to study the records of serum disease as observed in the Durand Hospital since its establishment, nineteen years ago, and to discuss in a brief manner some of the pertinent questions

FREQUENCY

Of the 2,859 patients who received diphtheria antitoxin, 804, or 28 1 per cent, showed serum reactions; of the 876 patients who received scarlet fever antitoxin 198, or 22 7 per cent, showed reactions, and of the 55 patients who received antimeningococcus serum 45, or 81 8 per cent, showed reactions These figures do not include all of those who received serum but only those patients who were observed for ten days or longer; those who died before ten days or were discharged before that time are not included in the series

The incidence of serum disease has varied in different reports, and the statistics from hospitals in which considerable numbers of cases have been observed have given the proportion of reactions from 14 to 50 per cent. It seems that the number of reactions may vary with the particular serum, and especially with the amount injected In hospitals such as the Durand Hospital, where many late and severe cases of diphtheria, including laryngeal cases, are admitted, the amount of antitoxin given is often relatively large and the reactions are correspondingly frequent

Several factors enter into the determination of the frequency of reactions One is individual susceptibility, which varies greatly Another is the toxic element of the horse serum The opinion has been expressed [1] that the serum of certain horses is more likely to cause serum disease than that of other horses Fresh serum is, as a rule, more prone to cause reactions than serum that has been preserved for some time The toxicity of fresh serum decreases rapidly during the first ten days A slight decrease occurs during the first two months, after which the deterioration is extremely gradual Besredka found that serum twenty years old produced anaphylactic shock in a sensitized animal Another factor is the previous introduction of serum As many patients nowadays receive toxin-antitoxin or other forms of immunization, the percentage of reactions on subsequent serum administration may be numerous Perhaps the most important factor in determining the occurrence of reaction is the quantity of serum injected The quantity of serum given in this series in the cases observed for ten days or more is given in table 1 It will be observed that the percentage of reactions increases as the quantity of serum increases In the series receiving the larger doses, the relatively small number of cases deprives the relative percentages of much value Of the patients receiving 10 cc or less of serum, 14 3 per cent gave reactions, of those receiving from 10 to 30 cc, 23 8 per cent gave reactions, of those receiving from 30 to 50 cc, 37 per cent gave reactions, of those receiving from 50 to 100 cc, 44 8 per cent gave reactions, and of those receiving 100 cc, and over, 61 7 per cent gave reactions The increased frequency of reactions with increased dosage has been mentioned by practically all authors

Contrary to the opinion of some, the reactions after the injection of scarlet fever antitoxin are not more numerous or more severe than after the use of diphtheria antitoxin In fact, the frequency of reactions in this series is slightly less, being 22 7 per cent as compared with 28 1 per cent for diphtheria notwithstanding the fact that many patients with scarlet fever had been immunized with toxin-antitoxin or had had diphtheria antitoxin

TABLE 1—*The Frequency of Serum Reactions in Diphtheria Patients Receiving Different Quantities of Refined Diphtheria Antitoxin*

160 350	3	2	5	60 0	100 0
	804	2 055	2 859	28 1	34 1

The frequency of reactions in epidemic meningitis is much higher, owing in a great measure to the relatively large doses of serum injected In a series of fifty-five patients who received antimeningococcus serum, reactions occurred in 50 per cent of those who received from 10 to 50 cc of serum, in 75 per cent of those who received from 50 to 100 cc, in 85 per cent of those who received from 100 to 200 cc, and in 100 per cent of those who received more than 200 cc of serum

When the serum is injected intravenously, the incidence of serum disease rises rapidly and usually takes the form of an immediate reaction In this series of cases the immediate reaction occurred in 66 6 per cent of the patients who received from 1 to 10 cc, intravenously, in 84 6 per cent of those who received from 10 to 20 cc, and in 90 per cent of those who received from 20 to 30 cc On account of the severe reactions likely to occur after the intravenous injection of serum, this method of administration should be used only in severe and neglected cases in which inadequate doses of or no antitoxin had been administered before admission

One gets the impression that the frequency of serum disease occurs less in Negroes than in white people, but no exact study has been made of this question

While the incidence of the natural allergies increases rapidly in the early age periods, the age incidence of

[1] Park, W H, and Thorne, B Am J M Sc 132: 686 (Nov) 1906

serum disease seems not to change during life. This is shown in table 3. The percentage of incidence of serum disease is practically the same for the different age groups.

Much effort has been expended with the purpose of lessening the property of horse serum of inducing serum disease. Rosenau and Anderson[2] stated that refined antitoxic serum, precipitated and dialyzed in accordance with the Gibson method, is quite as toxic, bulk for bulk, as the untreated serum from which it was obtained. Park and Thorne,[1] however, state that the concentrated antitoxin (Atkinson-Banzhaf method) materially reduces the tendency to serum disease They admit, of course, that the portion of the globulins still accompanying the antitoxin is capable of causing serum disease In comparing the frequency of serum disease, in an analysis of 692 cases in which whole serum was administered, with the reactions in this series, Weaver[3] found very little difference in the percentage of serum reactions during the years 1906 to 1908. Of the 692 cases observed for ten days or more reported by Weaver, 34.1 per cent presented reactions, while in the 2,859 cases reported in this series 28.1 per cent showed reactions Be that as it may, the treatment of serum by the various methods of concentration increases its antitoxic power, and a distinct advantage is obtained, so far as bulk is concerned, for the serum reaction depends partly on the quantity of serum given.

DAYS ON WHICH REACTIONS OCCURRED

As observed in this series, the interval between the injection and the appearance of the reaction varies from a few minutes to thirty days Table 4 shows the number of cases falling on the different days. Of the 804 cases with reaction after the injection of diphtheria antitoxin, in 690, or 85.8 per cent, the reaction occurred before the eleventh day. The largest number of reactions fell on the days from the sixth to the eleventh. A reinjection carried out during the normal incubation period following the first injection, that is, within from eight to twelve days, exerts no influence on the incubation period or the frequency or duration of the rash. If the reinjection is given after three weeks following the primary injection, the resulting reaction takes place, on the average, after distinctly shorter incubation than the normal period—the accelerated reaction of Pirquet and Schick.

SYMPTOMS

The ordinary serum disease following a first administration of horse serum is rarely of such severity as to threaten the life of the patient—it is a source of annoyance rather than of danger; but the immediate reaction following a repeated injection or in those who are sensitive to horse serum is apt to be more apprehensive. The symptoms of serum disease following a primary injection of serum are fever, skin eruptions, edema, swelling of the lymph glands, leukopenia and joint pain. These occur in various combinations, one being most prominent in one case, another in another. All may occur in a given case or most may be absent.

Total number of cases	804	193	45

In a considerable number of cases the reaction remains local. It was noted in this series and has been reported by others that the local reactions occur earlier than the general, and that they usually run an afebrile course, with little or no general disturbance. Occasionally after a rather early local reaction at the site of the injection of the serum and after an interval of several days, a general reaction occurs. Recurrent attacks of serum disease following a primary injection were observed in several cases and may be explained as separate reactions to the specifically different proteins of the serum. These recurrent attacks occur not only with whole serum but also with refined serum.

The most typical of serum reactions begin with local swelling at the site of the injection, the surrounding skin showing urticarial wheals and erythema. Soon the urticaria becomes general over the body, accompanied by severe itching. Fever often precedes and accompanies the exanthem and sometimes persists after its disappearance. The lymph glands adjacent to the site of the injection show enlargement and may be tender to the touch, and there may be enlargement of the lymph glands throughout the body. With the general urticaria the patient is restless and irritable or he may be drowsy.

[2] Rosenau and Anderson Bull 36, Hyg Lab, U S P H & M H S, 1907

[3] Weaver, G H Serum Disease, Arch Int Med 3: 485 (June) 1909

The edema of serum disease usually affects the face and dependent parts of the body. It is especially prominent in the loose tissues of the eyelids, hands and feet, and lips, which may be so swollen as to disfigure the features completely. The urticaria usually disappears as suddenly as it comes, and the fever and general ill feeling usually subside with it. The urticaria is usually of short duration, only occasionally lasting three or four days. In one case of the series the urticaria lasted for five days, in two cases for seven days and in one case eight days. The larger the quantity of serum given, the more severe are the symptoms likely to be, although occasionally a severe reaction occurred after the injection of a small quantity of serum.

The eruption of serum disease is usually urticarial, though it may be scarlatiniform and morbilliform or present the type known as multiform exudative erythema. Next to urticaria, a simple erythema is most common. This may be limited to the skin about the injection, or it may extend over a large part of the body. It is often associated with urticarial lesions. The redness disappears on pressure and is usually transient, lasting from one to three days.

Fever is inconstant. Cases of severe urticaria may run an afebrile course. In many cases there is a prodromal fever for a day preceding the eruption, but more often the fever appears at the same time as the eruption.

Pain in the joints may occur as the only symptom of serum disease, but usually it precedes, accompanies or follows other manifestations. More or less joint symptoms were observed in 24 per cent of the cases of this series. In some the pain was severe and persistent; in others, slight and transient, and in some cases only a stiffness was complained of. The pains are spontaneous, increased by motion and sometimes by touch. After from one to three days the pains disappear, leaving the joints without permanent alteration. Swelling of the joints is unusual. The joints most often involved are those of the hands and the knees, although any of the joints may be involved, and often several are affected simultaneously or in succession.

A slight transient albuminuria may occur, although infrequently. Leukopenia has been noted also. The mucous membranes are usually unaffected but in some cases in this series there was swelling of the tongue and of the lining of the throat. Involvement of the respiratory mucous membrane was observed in several cases, as evidenced by hoarseness and cough. Mucous membranes that have been the seat of the diphtheritic process are more prone to swelling at the time of serum reaction. Such phenomena were observed rather frequently in cases of laryngeal diphtheria. After all the laryngeal symptoms had disappeared for several days, with the onset of the urticaria the children again became very hoarse and croupy, but this was never severe enough to require intubation.

Disturbances of the stomach, as shown by local discomfort, nausea and vomiting, were observed in several cases.

More or less general disturbance accompanies all cases of severe serum reaction. Adults sometimes complain of headache, backache and severe aching in the muscles. In the more severe cases there is a considerable degree of prostration; the pulse is weak and irregular, and the symptoms of shock appear.

A more serious form of serum disease, the so-called immediate reaction of Pirquet and Schick, sometimes occurs in persons who have been rendered hypersensitive by previous injections of serum or in some manner of which we are ignorant. The height of sensitiveness after an injection of serum is reached in two or three months, after which the sensitiveness gradually declines but probably never disappears completely. Accelerated reactions have been observed nine and fourteen years after a primary injection. Following the second injection of serum after the normal incubation period, that is, from eight to twelve days after the first injection, there is occasionally no acceleration of reaction, but, if accelerated, it may be moderately or markedly so, the last being the so-called immediate reaction. Such reactions may be local or general. In the immediate local reaction an intense edema appears at the site of the injection a few minutes or hours after the secondary injection, reaches its height in twenty-four hours, and gradually subsides in from two to five days. Two cases of severe local reaction occurred in this series. One of these is cited to show the intensity which the reaction may assume.

A girl, aged 14, was admitted as having diphtheria and was given 40,000 units of diphtheria antitoxin in the lateral aspect of the right thigh. She had had toxin-antitoxin two years before, and a serum reaction developed with urticaria and edema, on the second day. The reaction subsided within twenty-four hours. Three days after admission and after the serum reaction had subsided, scarlet fever developed,[^] as she had been exposed before admission. On the fourth day after admission she was given one therapeutic dose of scarlet fever antitoxin in the lateral aspect of the right thigh but not at the site of the injection of the diphtheria antitoxin. Within twelve hours the right leg was swollen, edematous, indurated and very painful. The swelling and induration extended for 4 inches above Poupart's ligament and to the ankle. There were small subcutaneous hemorrhages at the site of the injections. With local treatment and epinephrine hypodermically the condition subsided and within eight days there was no evidence of a reaction.

In the local reactions, slight chilliness and fever were often observed. In several cases of the series there was a general immediate reaction, which appeared in from a few minutes to twenty-four hours and, in addition to the usual signs and symptoms of serum disease, was accompanied by severe asthmatic forms of dyspnea, cardiovascular disturbances with cyanosis, collapse, chills, nausea and vomiting, and occasionally renal disturbance including complete suppression of urine for several hours. In this category belong the cases that may prove fatal. However, no deaths have occurred.

If the second injection is given when hypersusceptibility is not marked, as, for example, after a small primary dose or several years after a primary injection, the accelerated reaction is not likely to be immediate but appears in from two to five days. Under these circumstances the reaction may appear as an ordinary case of serum disease or may be more severe.

No case of death that could be ascribed to injected serum occurred in this series. Immediate reactions of more or less severity have occurred in 58 of the 804 cases of serum disease after the injection of diphtheria antitoxin, and in 16 of the 198 cases of serum disease after the injection of scarlet fever antitoxin. Most of these reactions occurred after the intravenous injection of serum. However, careful desensitization is carried out on all patients before serum is given, and epinephrine is usually given at the same time as the serum.

The method of desensitization varies with the individual. If there is no history of previous administration of serum and no history of hives, hay fever or asthma, 5 minims of undiluted serum is given subcutaneously and doubled at thirty minute intervals until 1 cc. has been given. If no symptoms develop with 1 cc. of the undiluted serum, the full dose of antitoxin is given. If there is a history of previous administration of serum or a history of hives, hay fever or asthma, desensitization is carried out by injecting subcutaneously 3 minims (0.3 cc.) of a 1 : 10 dilution of the serum and increasing the amount injected at thirty minute intervals until 1 cc. has been given. Then from 0.5 to 1 cc. of the undiluted serum is given subcutaneously and if no reaction occurs the full dose is given. The time required for desensitization and the amount of serum injected for this purpose depend on the state of hypersensitiveness observed.

TREATMENT

In the *treatment of ordinary serum disease, nothing* new is offered. Many vain attempts have been made to prevent the occurrence of serum disease by desensitization and other methods. The administration of calcium salts is rational with the purpose of combating the edema. It seems to have little effect in preventing the reaction. Calcium gluconate, 1 drachm and 2 drachms (4 and 8 Gm.) three times a day with additional milk feedings in the morning and afternoon for ten days, was tried in a series of 107 patients who received scarlet fever antitoxin, but the percentage of reactions, 24.3, and the intensity of the reactions were not affected. A series of 98 patients who received diphtheria antitoxin received the same treatment but the percentage of the reactions, 37.9, and the intensity of the reactions were not affected. Intravenous administration of 1 Gm. of calcium gluconate two or three times a day has been tried after the serum reaction developed, and in some cases it seemed to have a tendency to allay the symptoms; in others it was without effect. It is perhaps less efficient in this respect than calcium chloride, the only advantage being the facility with which it is administered. Sodium thiosulphate intravenously has been tried in a small number of cases but without marked benefit. Solution of epinephrine hypodermically will allay the itching and cause the disappearance of the urticarial wheals, but its action lasts for only an hour or two, at which time the symptoms reappear with equal severity. Repeated injections of epinephrine together with morphine have given the best results in alleviating the symptoms. Ephedrine by mouth is much less effective. If collapse occurs, following the administration of serum, the treatment follows the directions indicated in conditions of collapse and shock in general. Hypodermic injections of rapidly diffusible stimulants, such as epinephrine and atropine, the administration of physiologic solution of sodium chloride and the like are to be employed. It is best, in our experience, to give small doses of epinephrine solution, which may be drawn into the syringe and injected at the same time as the serum to prevent the immediate reaction instead of employing the drug after the symptoms have developed. This procedure has given good results and is used as a routine in cases in which an immediate serum reaction seems likely to develop.

CONCLUSIONS

Serum disease occurred in 28.1 per cent of 2,859 patients who received diphtheria antitoxin, in 22.7 per cent of 858 patients who received scarlet fever antitoxin, and in 81.8 per cent of 55 patients who received antimeningococcus serum.

The occurrence of a serum reaction after the injection of diphtheria and scarlet fever antitoxin is determined in part by the susceptibility of the individual, by the toxic properties of the serum, and, in the largest measure, by the total quantity of serum given. Concentrated diphtheria antitoxin calls forth reactions in about the same proportion as does whole serum in corresponding bulk.

The serum reactions after the use of scarlet fever antitoxin were slightly less in frequency than those after the use of diphtheria antitoxin. They were not more severe.

The incidence of serum disease does not vary widely in the various age groups.

The interval between the injection and the appearance of the reaction varies from a few minutes to thirty days. The *majority of the reactions appear before the eleventh day.*

637 South Wood Street.

ALLERGIC MIGRAINE

ALBERT H. ROWE, M.D.
OAKLAND, CALIF.

In a recent review of the subject of allergic migraine, I[1] stated that Vaughan,[2] in 1922, was the first to report two cases of migraine due to food allergy and that in 1927 he[3] reported ten other cases. Laroche, Richet and Saint Girons,[4] in 1919, had suggested that migraine might be due to food sensitization. In 1927 I[5] stressed food allergy as a cause of migraine in two different articles, and in 1928 I[6] reported forty cases with allergic migraine relieved with elimination diets. In 1930, in an article on allergic toxemia and migraine, eighty-six cases of such headache were analyzed.[7] Balyeat[8] cited one case of allergic migraine in 1928, two cases in 1929 and fifty-five cases in 1930. Recently, he and Rinkel[9] have studied 202 cases of migraine from the allergic point of view and have emphasized the frequency of migraine in children.[10] Beecher[11] reported four cases in 1929. Eyermann,[12] in 1931, reported good results in 69 per cent of a group of sixty-three patients with headaches. The causative foods were determined by diet trial based on slight or positive skin tests and confirmed by diet trial.

[12] Eyermann, C. H.: Allergic Headache, J. Allergy **2:** 106 (Jan.) 1931.

Phillips[13] has affirmed the frequency of food allergy as a cause of migraine and has recommended the elimination diets in its control. This completes the summary of the contributions that have established food allergy as a frequent cause of migraine.

Woltman,[14] in 1925, stated that migraine was usually hereditary and protean in its manifestations. He emphasized the fact that migraine might be mild or severe, occurring in any part of the head, evidencing itself in a dull headache, in transient scotoma or in periods of mental depression or inertia or by transient paresis, paresthesia or aphasia. He said that most so-called gastric or bilious headaches are migrainous in type. The severe type of migraine at times suggested brain tumor and often lasted many days, being associated with severe nausea and vomiting and great exhaustion and mental depression. This variability of symptoms corresponds with the experience of other students of migraine. In his classic monograph on migraine, Liveing,[15] in 1873, emphasized the periodicity, the disturbances in sight, speech, tactile sensations and psychic functions, the drowsiness, dizziness, headache, nausea, vomiting and the frequent association of migraine with epilepsy, spasmodic croup and asthma. Thus, migraine includes a wide variety of symptoms associated with headaches and as such is considered in this contribution.

Allergy as a cause of migraine has been considered in other articles during the last two decades. Tileston,[16] in 1918, commented on the similarity of migraine to asthma and reported headaches in one boy which were due to eggs, meat and fish. Brown,[17] in 1920 and in 1925, reported headaches arising from various foods and he felt that they were due to protein poisoning. His skin tests were all negative. Moloney,[18] in 1928, stated that migraine was most frequent in patients who had a personal or familial history of allergy. Allergy as a cause of migraine was also considered and discarded by T. R. Brown[19] in 1921 and more recently in 1929; by Minot[20] in 1923; by McClure and Huntsinger[21] in 1927 and 1928; by Laing[22] in 1927; by Hartsock[23] in 1927, and by Stevens[24] in 1929. Most of these writers felt that migraine was due to hepatic dysfunction, indigestion, endocrine disturbances, fatigue, nervousness and various other causes. However, no reports of successful results exist comparable to those which have been recorded from the elimination of allergic foods, showing that these hypothetic considerations have not been of marked value in the control of migraine. The occasional benefit derived from carbohydrate or protein free diets reported by Brown, Minot and Hartsock could have resulted from the elimination of allergenic foods in such diets. Several of these writers warned against the futility of abdominal or nasal surgery and of the extraction of teeth and were discouraged with the results from the control of ocular strain or defects.

TABLE 1.—*Statistics on One Hundred and Thirty Private Patients with Headache as a Major Complaint*

Ages	No. of Cases	Personal History	No. of Cases
10-15	1	Nasal congestion	44
15-35	39	Hay fever	20
35-55	70	Bronchial asthma	6
55 up	20	Chronic indigestion	53
		Nausea	71
Males	31	Vomiting	51
Females	99	Abdominal pain	25
		Mucous colitis	6
Duration of Symptoms		Constipation	57
½-1 year	9	Diarrhea	15
2-5 years	26	Eczema	26
Over 5 years	95	Urticaria	39
Family History	No. of Cases	Operations with No Relief to Headaches	No. of Cases
Family history (positive)	90 (69.2%)	Appendectomy	11
		Cholecystectomy	7
Headache	56	Intestinal obstruction (not found)	2
Asthma	30	Ovarian cysts	2
Hay fever	15	Hysterectomy	1
Eczema	5	Curettement	2
Urticaria	7	Artificial menopause (radium)	2
Chronic indigestion	21	Nasal surgery	11
Skin Reactions		Tonsillectomy	5
Foods	23	Extraction of teeth	4
Inhalants	15	Spinal puncture	1
Miscellaneous	7	Total	48

In the consideration of allergic migraine, the other causes of headache, such as sinusitis, eye strain, arteriosclerosis, arthritis, focal infections, nephritis, brain tumors and pelvic disorders must be considered and kept in mind in the differential diagnosis. Thorough diagnostic studies including all types of laboratory investigations indicated by the patient's history and physical conditions must be carried out in each patient, so that headaches due to any of the causes named may be recognized. Allergic migraine, however, occurs in patients with other types of pathologic changes, treatment of which without proper elimination diets is not effective in the control of the headaches.

PERSONAL STUDIES

Statistics on 130 private patients, one of whose major complaints was headaches, are presented and the reported relief is based on a recent follow-up in each case. My studies have been largely confined to adults. However, in many of the patients the symptoms started in childhood, as shown by the data on the duration of symptoms. Moreover, the literature emphasizes the frequency of migraine in youth, when it is probably often overlooked or ignored. Most of my patients had had their symptoms longer than five years, and the majority of them had nausea or vomiting associated with their headaches. Personal history of conditions which are frequently due to allergy is shown in table 1. Hay fever, nasal congestion, hives and eczema were especially common in comparison with other disturbances.

The family history was positive for allergy in 69.2 per cent and gave a history of migraine in 43 per cent, of asthma in 23 per cent, and of hay fever in 11.5 per cent of the 130 patients.

Operations of various types, as indicated in table 1, had been performed without relief to headaches. Of these, appendectomy, cholecystectomy and nasal operations were most frequent. With the use of elimination diets, modified by history and skin reactions, good results occurred in 73.1 per cent of this series of 130 patients with headache; failure occurred in 20 per cent; fair results occurred in 6.9 per cent. Of the 109 patients who gave good cooperation, good results occurred in 87 per cent. These results compare with those of Eyermann,[12] who recently reported good results in 69 per cent of a series of 63 patients, and of Balyeat,[9] who recently reported definite results in 88 per cent of 202 cases. Most of my patients had tried other types of therapy for the relief of their symptoms.

An analysis of the patients who obtained only fair results or no results at all is profitable. Of these thirty-five patients, twenty-one gave poor cooperation in following their diets. Good cooperation, however, was given by fourteen patients who failed to obtain results.

Miss R. continues to have headaches in spite of strict adherence to various elimination diets. All types of examinations have been negative. Two ophthalmologists found nothing abnormal in her eyes. She has had long courses of ovarian and pituitary extracts hypodermically, and nonspecific protein therapy has been used—all with no effect. The possibility of a psychologic problem has been considered.

Mrs. B. is undernourished, is nervous, and gives large skin reactions to all types of pollens and animal emanations and many different foods. She has had the uterus and gallbladder removed, but her headaches persist.

Mrs. L. has recurrent headaches, unaffected by various types of elimination diets. She has marked duodenal stasis which indicates pathologic changes in the upper quadrant. Operation has been refused.

Mrs. H. likewise has pathologic changes in the upper part of the abdomen together with a trigeminal type of neuralgia. Elimination diets have failed to produce relief.

Mrs. L. and Mrs. A. H. have severe recurrent migraine, which has not yielded to elimination diets. Repeated duodenal drainage, hypodermics of ovarian and pituitary extracts, intravenous and subcutaneous peptone and psychotherapy have been unavailing in each patient.

Miss C. had extensive nasal surgery before I saw her and complained of great fatigue and nervous exhaustion. Elimination diets were ineffective.

Miss H. had excellent results from the elimination diets for one year. Since then she has apparently developed sensitizations varying from mild to severe ones to practically all foods and at present is fairly free from her symptoms on a restricted elimination diet which maintains her weight and strength.

Mrs. L. and Miss W. have had no relief from the elimination diets and have tried many other diets and forms of medical therapy for many years without relief. Physical and laboratory examinations of these patients by several other internists have been negative. Mrs. R. has large reactions to practically all types of pollen and many foods. A diet free from all allergenic foods has not been possible and the effect of her extensive pollenosis has not been determined. Mrs. C. was not benefited by elimination diets and it was felt that nervous influences were responsible for her migraine.

Miss C. likewise is extremely nervous and introspective. Cholecystectomy had given no relief, and no help was obtained from diet trial over a period of six months.

Mrs. E. has had headaches of the worst type all her life. Pelvic surgery and cholecystectomy had given no help. Elimination diets, duodenal drainage, intravenous peptone, peptone and trypsin by mouth and stool vaccines have been entirely useless.

Thus these patients, who were not helped by elimination diets, were not benefited through other forms of therapy. This again emphasizes the importance of food allergy in the etiology of this malady, especially in view of the fact that 73 per cent of my 130 patients, 69 per cent of those reported by Eyermann[12] and a higher percentage of those recently reported by Balyeat[9] obtained good results from the elimination of allergenic foods.

It is evident that all patients with migraine, as well as those with mild types of headache and migrainous equivalents, must be studied with allergy in mind.

PATHOGENESIS

A localized edema of the cerebral tissues or localized spasms of cerebral blood vessels may be the cause of the migrainous symptoms. Vomiting may be of central origin or may be due to localized allergic disturbances in the gastro-intestinal tract or in the liver itself. The hepatic swelling with associated icterus, which has been reported through the literature in certain patients during attacks of migraine, may be due to such localized allergy in the hepatic tissues.

As localized allergic reactions occur in the cerebral tissues, so they undoubtedly arise in the tissues of the spinal cord and peripheral nerves, causing various nervous symptoms, chief among which is peripheral neuralgia in various parts of the body.

DIAGNOSIS AND TREATMENT

My previous publications[1] have described the method of diagnosis and the use and development of my elimination diets for the determination of food allergies. In brief, certain patients are relieved by the exclusion of those foods to which positive skin reactions or a history of definite food idiosyncrasies exist. However, most adult patients fail to give satisfactory skin reactions to allergenic foods, and in most instances it is advisable to use diet trial, excluding those foods which most frequently produce allergy. For this purpose, my elimination diets have been of increasing value during the last five years.

Table 2.—*Results and Cooperation in One Hundred and Thirty Patients with Headaches from the Use of Elimination Diets*

Cooperation	Number of Cases	Results	Number of Cases	Per Cent
Poor	11	Failure	26	20
Fair	10	Fair	9	6.9
Good	109	Good	95	73.1

Good results demand absolute cooperation of the patient over a period of weeks or months. The slightest break in the diet, especially in the first few weeks, often precipitates migraine. Gradually the individual's tolerance for the offending foods can be determined and, with their continued elimination, desensitization may gradually occur.

It has been my experience that little help can be obtained from any measures other than the exclusion of allergenic foods from the diet in patients with allergic migraine. Occasionally the hypodermic administration of 5 per cent peptone seems to be of help, especially in those patients who have sensitizations to practically all types of food. Peptone by mouth has been disappointing. The possibility of migraine arising from inhalant or bacterial allergy exists, but definite proof of such etiology is not available. Treatment for the relief of anemia, nervousness, indigestion due to various causes, including achylia and deficiency in digestive ferments, and the control of all other pathologic states undoubtedly is of aid in the control of migraine due to food allergy. But without absolute adherence to the prescribed elimination diet, allergic migraine cannot be successfully eradicated.

CONCLUSIONS

1. Food allergy as a frequent cause of migraine has been demonstrated.

2. Of 130 patients, good results with the elimination of allergenic foods occurred in 87 per cent of the 109 patients who gave good cooperation.

3. My elimination diets, modified by positive skin reactions or a history of idiosyncrasies to specific foods, have been effective in the determination and control of the food allergy.

Clinical Notes, Suggestions and New Instruments

SILICOSIS IN A TUBERCULOSIS HOSPITAL

Jerome R. Head, M.D., and Samuel H. Rosenblum, M.D
Associate in Surgery, Northwestern University Medical School, and
Resident Physician in Tuberculosis, Cook County
Hospital, Respectively
Chicago

The present paper is a report of a clinical and statistical study of pneumonoconiosis in a general tuberculosis hospital in a district in which the industries do not especially predispose to this condition.

It is well known that silicosis predisposes to tuberculosis and that the tuberculosis mortality among workers in silica dust is from ten to twenty times higher than that of the general population. Britton and Head[1] have recently emphasized the fact that silicosis develops slowly and that frequently many years intervene between the cessation of exposure to the dust and the appearance of symptoms. Not infrequently the first symptoms are those of a superimplanted tuberculosis.

Knowledge of these facts led us to believe that a careful search through a large tuberculosis hospital would reveal many instances of tuberculosis secondary to silicosis and would be valuable in affording some idea of the importance of this condition in the general tuberculosis problem. We expected that in the Chicago area, which like any large city is more or less the center of gravity for a large shifting population, we would encounter many instances in which the exposure had occurred in distant localities and in which many years had elapsed between the cessation of exposure and the development of symptoms.

Table 1.—*Incidence of Silicosis in Five Hundred Cases of Tuberculosis*

Ages	Number of Patients	Cases of Silicosis	Percentage
20 to 30	182	0	0
30 to 40	105	3	3
40 to 50	116	9	8
50 to 60	81	4	5
60 and over	16	1	6

Five hundred male patients, admitted consecutively to the tuberculosis wards of the Cook County Hospital, were carefully questioned. A complete industrial history was taken of each patient from the time he started work until he was admitted to the hospital. Among the 500 patients there were discovered 17 (or 3.4 per cent of the total) who had definite silicosis.

Since silicosis is an occupational disease and one which develops very slowly, it occurs most often in late adult life. Tuberculosis has its highest incidence in the years of adolescence and those closely following. One would expect, therefore, that more of the older tuberculous patients would have silicosis than of the younger. This was found to be the case. Table 1 shows the incidence in the different decades. The average age was 45 years.

There were no instances among those under 30 years of age; of the 318 patients over 30, 5.3 per cent had silicosis, while of those over 40, the percentage was 6.6. The highest incidence, 8 per cent, occurred in the fifth decade.

Table 2 shows the nature, location and duration of the exposure as well as the interval between the cessation of exposure and the onset of symptoms.

Table 2—*Source, Location and Duration of Exposure*

Age	Nature of Work	Duration of Exposure	Free Interval
43	Coal mine in Pennsylvania	1 year	15 years
31	Lead and zinc mines in Missouri	5 years	0
47	Coal mine in Pennsylvania.	10 years	18 years
60	Coal mine in Pennsylvania	20 years	10 years
52	Sandblasting	10 years	0
47	Sandblasting	5 years	10 years
48	Copper mine	1 year	15 years
42	Sandblasting.	1 year	4 years
46	Coal mine in Poland	3 years	7 years
38	Coal mine in Pennsylvania	4 years	18 years
56	Lead, zinc and iron mines	35 years	0
50	Coal mines in Pennsylvania.	10 years	5 years
42	Coal mines in West Virginia	2 years	
	Cleaning dies in foundry	5 years	0
52	Rock heading soft coal mine	2 years	9 years
47	Sand shoveling in foundry.	6 years	6 years
32	Sandblasting	10 years	0
40	Mining	?	?

Mining and sandblasting accounted for all save one of the seventeen cases; twelve of the patients were miners, four sandblasters and one had shoveled sand in a foundry for six years Of the twelve miners, nine had mined coal, two lead and zinc and one copper. Of the nine coal miners, five had worked in the Pennsylvania mines, one in those in West Virginia, one in Poland, for one the location was not stated and one had done rock heading in a soft coal mine for two years

In different parts of the country the origins of the silicosis will be different. It is of particular interest that in the Chicago area such a large percentage of the cases originated in the Pennsylvania coal fields, a smaller percentage in the lead, zinc and copper mines of the West and an even 25 per cent in local industries. Immigrants, especially from the slavic states of central Europe, stop first on the Eastern seaboard, many of them finding work in the Pennsylvania mines. After working there a number of years, many of them seek better conditions and more congenial work in Western cities. Of these, Chicago gets its share. It was often many years after they had reached Chicago that the effects of the dust became manifest.

Only four of the patients developed symptoms while still engaged in the dusty work; two of these were sandblasters and two were lead and zinc miners. In the other twelve there was an average interval between cessation of work and onset of symptoms of 10.75 years, with low and high limits of four and eighteen years, respectively. The average duration of exposure was eight years, with low and high limits of one and thirty-five years, respectively.

The diagnosis of silicosis and tuberculosis is made on three bases: a history of exposure to dust, a characteristic roentgenogram, and the finding of tubercle bacilli in the sputum. All these must be positive, for the roentgenogram of simple silicosis can closely simulate tuberculosis, and some types of tuberculosis can closely simulate silicosis. There are, furthermore, conditions other than tuberculosis which can be confused with pneumonoconiosis.

The history must be investigated with great care. The exposure may have been many years in the past and of only

---

From the tuberculosis wards of the Cook County Hospital.

[1] Britton, J. A., and Head, J. R.: Pneumonoconiosis, J. A. M. A. **96**: 1938-1939 (June 6) 1931.

short duration. The patient may have forgotten it or may not have recognized that it was an exposure. In the face of a characteristic roentgenogram, one should go over and over each period of the patient's industrial history. Pancoast cites an instance of a positive roentgenogram in the case of a tap dancer. No history of exposure could be determined until the patient volunteered the information that he had scattered sand on the stage before each performance. We recently saw a patient whose lungs were marked by silica just as plainly as if the word were written there and yet who swore that he had never done anything save farming and butter making.

The roentgenogram is of first importance in the diagnosis. First stage silicosis, characterized merely by an increase in the hilus shadows, cannot be recognized unless the history of exposure is known, and even then it is a more or less doubtful entity. Second stage disease, on the other hand, gives one of the most characteristic of roentgenograms. The miliary bronchial nodules radiating from the hilus into the lung fields, affecting principally the middle areas and sparing the apexes and bases, are almost diagnostic. The picture can be simulated only by miliary tuberculosis, passive congestion, miliary carcinosis and some rare fungous infections.

In the third stage there is a coalescence of the miliary nodules with the formation of large areas of increased density often affecting a whole lobe. This stage closely simulates fibroid tuberculosis, and it is difficult to say in any given instance whether or not tuberculosis is also present. Cavities or a pleural effusion practically always mean tuberculosis, and fever and systemic symptoms suggest it strongly. The diagnosis can be confirmed only by the finding of tubercle bacilli in the sputum, and in this type of tuberculosis they are often difficult to find.

In the present series there is the probability that some of the patients had pneumonoconiosis uncomplicated by tuberculosis and were in the hospital under a mistaken diagnosis. Examination of the roentgenograms and clinical records suggests strongly that this was the case in at least two instances. The sputum was positive in all save five cases. In three of the five, the roentgenograms showed obvious tuberculosis with cavitation. In fifteen of the seventeen one can say definitely that tuberculosis was present. In two it is probable that there was no tuberculosis.

If a patient has silicosis without tuberculosis, he should not be allowed in a tuberculosis hospital, much less confined there. No other group of individuals is so susceptible to the disease. This fact should be borne in mind and pains taken to distinguish the two conditions. As has been said before, this is often difficult; for the roentgenographic signs in third stage silicosis are practically identical with those of certain types of tuberculosis. The former condition, however, rarely causes fever or loss of weight and the physical signs are often absent or of a type to suggest bronchitis rather than tuberculosis. Constant post-ptussal râles over one or both apexes suggest tuberculosis. It is generally felt that pleurisy with effusion occurring in these cases is of tuberculous origin. Cavitation does not occur in uncomplicated silicosis and when present is practically certain evidence of tuberculosis. In many cases in the last analysis the presence or absence of tuberculosis must be determined by the examination of the sputum. In these cases, especially if there is no cavitation, tubercle bacilli are not abundant and often must be sought for repeatedly and by culture or animal inoculation of the sputum.

SUMMARY

1. Seventeen cases of silicosis or silicosis and tuberculosis, 3.7 per cent of the total, were found among 500 male patients admitted consecutively to the tuberculosis wards of the Cook County Hospital in Chicago.

2. Fifteen of these had silicosis and tuberculosis. In two a definite diagnosis of tuberculosis could not be established.

3. The condition, as was expected, was more frequent among the older patients. It was found in no patients under 30, in 3 per cent of those between 30 and 40, in 8 per cent of those between 40 and 50, in 5 per cent of those between 50 and 60, and in 6 per cent of those over 60.

4. In only 25 per cent of the cases was the exposure incurred in Chicago or its vicinity. In the majority of instances it was in mining, principally in the coal mines of Pennsylvania and West Virginia and in the metal mines of the West.

5. In all save four cases there was a free interval between the cessation of exposure and the appearance of symptoms. The average interval was 10.75 years. The low and high limits were four and eighteen years, respectively.

104 South Michigan Avenue—3245 Fullerton Avenue.

Council on Physical Therapy

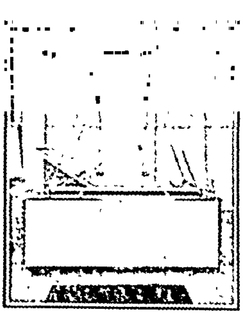
The Council on Physical Therapy of the American Medical Association has authorized publication of the following report.

H. A. Carter, Secretary.

LANG HOSPITAL INSULATED PROLONGED FLOWING BATH WITH HAMMOCK ACCEPTABLE

The Lang Hospital Insulated Prolonged Flowing Bath with Hammock is manufactured by William J. Lang of Chicago and is designed for general hydrotherapy treatments.

The sides and the bottom of the bath are made of two thicknesses of 1 inch veneer and two thicknesses of compressed cork with an air space between the cork thicknesses. The inner lining, capping and corners are of stainless steel. The four outer sides are faced with white "Bakelite." The bath is supported by four marble blocks. This insulated construction is provided for the purpose of maintaining the temperature of the water. The inside dimensions of the standard equipment are: length, 6 feet 6 inches; width, 2 feet 6 inches, and depth, 2 feet 4 inches. However, by special order, the bath can be constructed to any desired dimensions.



Lang Hospital Insulated Prolonged Flowing Bath with Hammock.

The bath is equipped with a 3 inch combination waste and overflow, designed to allow an 8 inch variation in the depth of the water. All metal in connection with the waste and supply for the bath is brass, chromium plated.

A Powers Thermostatic Water Mixer designed to control the mixing of hot and cold water thermostatically and deliver a constant supply of warm water is a major part of the equipment.

The firm claims that the temperature of the water mixture remains so constant that it will not vary to within 0.5 degree F., plus or minus, regardless of temperature or pressure changes in the hot or cold water supply lines. There are never sudden "shots" of hot or cold water. Failure of either supply completely shuts off the delivery flow. Restricting the delivery flow has slight effect on the delivery temperature. The temperature range of the mixer is from cold water to 115 F.

The hammock is constructed of 1¼ inch angle iron with adjustable shoulder and head rests, brazed on all joints. Steelcane is welded between the frame, shoulder and head rests. The foot rest is made of white ash and has an 18 inch variation of adjustment. Rubber bumpers measuring 2½ by 3¼ inches are placed on the four corners of the hammock to prevent it from defacing the sides of the bath; also they act as rests when the hammock is lowered to the bottom of the bath. All metal parts of the hammock are thoroughly galvanized.

The lowering and raising device of the hammock is constructed of 3 inch galvanized steel posts and angle iron. The cables, swivel joints and unlocking devices are of bronze. The lowering and raising device is controlled by one lever, which holds the hammock and the patient at any desired position without locking of the lever.

An adjustable tray in connection with this bath is connected to the side of the bath and may be set at any desired height or position, allowing the patient to eat or read while under treatment. The shipping weight is about 400 pounds.

The Council declares the Lang Hospital Insulated Prolonged Flowing Bath with Hammock eligible for inclusion in the Council's list of accepted devices.

Committee on Foods

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION, AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

RAYMOND HERTWIG, Secretary.

CARNATION MALTED MILK

Manufacturer.—Carnation Company, Milwaukee.

Description.—A dried malted milk in tins.

Manufacture.—The product is prepared from whole milk, barley malt and malted wheat flour.

Coarsely ground barley malt, water and wheat flour are mixed in a nickel mash kettle equipped with an agitator and steam coils. A definite mashing temperature is maintained until the starch is converted to soluble carbohydrates relatively high in maltose and low in dextrins. The solid material is separated from the liquid in a sieving kettle with a perforated false bottom. The liquid is flowed over a fine mesh screen to remove coarse insoluble materials and further clarified by means of mechanical clarifiers. The clarified liquid containing protein and other substances in suspension is tested for total solids to determine the quantity of whole milk to be added to give the finished product a milk-fat content of not less than 8 per cent. Definite quantities of the liquid extract or "wort" and pasteurized whole milk are mixed, maintained at 54-57 C. for several hours and concentrated in "vacuum" to a desired density. (The absence of air tends to protect the natural vitamins present.) The condensed mixture is homogenized, cooled, and dried in a revolving drum "vacuum" drier in which the concentrated material is pumped against revolving steam heated drums, from which it is removed in dry sheets by knives. The dry sheets are broken in small pieces, discharged from the "vacuum chamber," cooled, finely ground and packed in tins with both a friction and a screw cover.

The equipment used is of pure nickel, glass-lined steel or tinned copper and is cleaned daily. The milk and raw materials are subjected to regular laboratory inspection and examination.

Analysis (submitted by manufacturer).—

	per cent
Moisture	2.7
Ash	2.3
Fat	8.4
Protein (N × 6.25)	12.8
Crude fiber	0.3
Carbohydrates other than crude fiber (by difference)	73.5
Chloride (Cl)	0.39
Sodium (Na)	0.42
Potassium (K)	0.37
Calcium (Ca)	0.25

Calories.—4.2 per gram; 119 per ounce

Claims of Manufacturer.—A malted milk for the preparation of table beverages.

HOLSUM SLICED BREAD

Manufacturer.—Miller-Patton Baking Company, Rockford, Ill.

Description.—A white bread made by the sponge dough method (method described in THE JOURNAL, March 5, 1932, p 817); prepared from patent flour, water, yeast, malt syrup, lard, a yeast food containing calcium sulphate, ammonium chloride, sodium chloride and potassium bromate, salt, sucrose, powdered skim milk and shortening.

Analysis (submitted by manufacturer).—

	per cent
Moisture (entire loaf)	35.1
Ash	2.0
Fat	2.6
Protein (N × 6.25)	10.0
Carbohydrates other than crude fiber (by difference)	50.0
Crude fiber	0.3

Calories.—2.6 per gram; 74 per ounce.

Claims of Manufacturer.—A bread of good quality.

CROWN BEST PATENT FLOUR—UNBLEACHED

Manufacturer.—Crown Mills, Portland, Ore.

Description.—An "all purpose" short patent flour milled from a blend of hard white wheat and hard red wheat; for home baking; not bleached.

Manufacture.—A blend of hard white wheat and hard red wheat is cleaned, washed, tempered, and milled by essentially the same procedure as described in THE JOURNAL, June 18, 1932, page 2210. Chosen flour streams are blended and automatically packed in cotton bags.

Analysis (submitted by manufacturer).—

THE PRIVATE PRACTITIONER AND PREVENTIVE MEDICINE

The physician of the future must be increasingly a practitioner of preventive medicine. Obviously this involves new relationships to the public and to the health official. Under various forms of state practice, problems have arisen which were discussed by Sir George Newman, K.C.B., M.D., F.R.C.P., chief medical officer of the Ministry of Health, who in his capacity as president addressed the Section of Public Health at the centenary meeting of the British Medical Association.[1] He pointed out that in no previous age has there been such growth of the conception of preventive medicine as in the present era, paying tribute to Bright, Addison, Hodgkin, Gull, Jenner, Osler, Allbutt and Barlow for the constructive service that has been rendered in the great march of preventive medicine by medical practitioners. "It is they," he said, "who have made the bricks, found the road, explored the facts, carried on the fight, and educated the people in a way of life." He elucidated further: "They searched into the circumstances of disease and related it to environment; they introduced medical notification and hospital isolation; by their investigation of factory conditions they initiated industrial welfare; they stemmed the rising tide of spirit drinking; they began the reformation of midwifery and were the first to attack the problems of child sickness and mortality; they established dispensaries and staffed the new hospitals; their systematic support of vaccination instituted the practice of immunity; and their scientific observation was the beginning of British epidemiology."

Sir George Newman then described the practitioner as a medical officer, pointing out how British physicians were responsible for the attention paid to preventive medicine in the Poor Law of 1834 and how they were the first to sponsor the Royal Commission of 1869. This commission first proposed a ministry of health, established fifty years later. He brought his historical review down to date through a consideration of the practitioner in insurance practice under the insurance act of 1911. What Sir George Newman had to say about the insurance act should be of interest to American physicians and, indeed, to American patients. He pointed out that "15,000 medical practitioners have voluntarily joined in a cooperative scheme of the profession, the friendly societies and the state for the medical supervision of fifteen million people, more than a third of the whole population, inclusive of the wage earners of the country."

Here is a significant development. These practitioners represent three sevenths of the number of physicians who are members of the British Medical Association. Translated into American terms, it would mean 45,000 physicians in this country affiliated with such a scheme if one should be established in the United States. And if the same proportion of our population were to be participants in it, there would be forty million beneficiaries.

Sir George Newman, as a government official, sees in the British health insurance plan little but benefit to the public and the profession. There are, however, those who differ with him in this opinion. For example, he said that these insured persons come to their chosen physicians frequently and undeterred at the beginning of sickness, when disease may be most effectually controlled. It is undoubtedly true that they come frequently and undeterred, as may easily be understood when it is realized that their sick benefits are paid for in advance and that it is but human to desire value received for money paid. Perhaps it may also be conceded that they come at the beginning of sickness, when disease may be most effectually controlled. Yet American investigators, who may be presumed to approach their investigation without bias, regard as the most startling fact about the vital statistics of insurance countries the steady and fairly rapid rate of increase in the number of days the average person is sick annually and the continuously increasing duration of such sickness.[2]

Nor does Sir Arthur Newsholme fully support the views of Sir George Newman as to the value of health insurance in preventive medicine. In 1920 Newsholme[3] said: "The chief justification of a national system of insurance against sickness is that it shall be an active auxiliary in the prevention of disease. At present it is doubtful whether any national system of sickness insurance has been so. It has only been so to the extent to which the medical treatment of the masses of the population has been improved by it; and no such improvement can be claimed for British insurance." In 1927 he did not seem to have changed his mind a great deal, for then he[4] pointed out that "the demands on insurance funds and on the expenses of official and voluntary child health work would be reduced to an almost incredible extent if the people were educated to practice the art of hygienic living." After sixteen years, health insurance had not, apparently, been a potent force in public health education in Great Britain.

[2] Simons, A. M., and Sinai, Nathan: The Way of Health Insurance, University of Chicago Press, 1932, p. 157.

[3] Newsholme, Sir Arthur: Public Health and Insurance: American Addresses, Baltimore, Johns Hopkins Press, 1920, p. 109.

[4] Newsholme, Sir Arthur: Health Problems in Organized Society, Westchester, P. S. King & Son, Ltd., 1927, p. 160.

These points of view are incompatible unless there exist elements in insurance practice which preclude the effective application of the principles of preventive medicine. Simons and Sinai[5] point out that the value of continuous records kept by insurance practitioners, which has been much stressed as an important point in favor of insurance practice, must be discounted because "examination of these [records] is sufficient to show that in their present form they are too indefinite and scanty to be of any great value as a guide to subsequent treatment."[6] Nevertheless, says Newman, "I have no doubt that health insurance is one of the most effective instruments of preventive medicine which we possess."

Sir George Newman points out the advantages of social insurance to the practitioner but does not speak of the disadvantages which Simons and Sinai[7] list: "(1) restrictions on treatment; (2) restrictions on prescribing; (3) free choice of doctor; (4) professional secrecy; (5) the required records, or 'red tape'; (6) entrance to insurance practice; (7) clinics; (8) certification." No doubt the British system[8] is superior to other systems in that the medical profession, through the British Medical Association, has a greater voice in the management of insurance practice than has the medical profession in other countries, notably Germany, where bitter criticism of the system is rampant.[9]

Medical practice in America today includes the activities of hospitals, clinics, medical schools and public health departments. Scientific research has opened new vistas for the prevention of disease, and increased costs of medical care, including prevention, diagnosis and treatment, are inevitable. That there will be some movement to solve the economic problem thus created is to be expected and that the movement will be sponsored by social workers and humanitarians is also to be anticipated. The implication that only a socialized attack on the problem of medical costs will solve the problem need not, however, be accepted by the medical profession.

Simons and Sinai[10] point out that the British Medical Association was not consulted in the original drafting of the insurance act and that it cost its treasury £30,000 in addition to other large special voluntary funds raised by the association to get a voice in the determination of conditions under which physicians should practice. In France the medical profession took a timely stand and succeeded in having a determining voice in the establishment of the French system. In our country, economists, sociologists, foundations and such large commercial interests as the insurance companies are taking an active part in influencing public opinion. Fortunately there is still time for the medical profession to take its proper place in the determination of how the problems of medical practice shall be solved. That determination need not and probably will not be a selfish one. Any proposal relating to health depends on medical service. Without adequate provisions for delivering a high grade of medical service the profession suffers, but the public, that is, the patient, suffers still more. Sir George Newman fails to point out what Simons and Sinai[11] regard as the fundamental defect in existing health insurance systems; namely, combining the work of the practicing physician with that of the examiner or inspector on whose judgment cash benefits are awarded. This conflict disturbs the relationship of faith and confidence between patient and physician, which students of medical practice have from the beginning regarded as fundamental. While the doctor is expected to act as an inspector, he cannot function to fullest advantage either in treatment or in prevention of disease. In the light of other opinions, Sir George Newman has not made out a very convincing case for health insurance as a public health measure, at least on the British plan. It seems, indeed, to have developed merely a cheap method of satisfying underprivileged workers with a less than adequate medical service.

THE PATHOGENESIS OF ADENOMATOUS (NODULAR) GOITER

Adenomas of the thyroid have for long been considered, largely from their morphologic similarity to adenomas elsewhere, as true benign neoplasms. Their origin has generally been attributed to the persistence of embryonal rests, even when present in the adult gland. This idea has persisted in spite of the absence of any actual convincing proof and has contributed to the confusion and difficulties so often encountered in any attempt to correlate the pathologic and the clinical pictures.

Experimental production of nodular goiter similar to these so-called adenomas has been reported recently by Cole and Womack[1] of the department of surgery at the Washington University School of Medicine. These workers studied the results of various factors, mostly chemical and infectious, which they had previously shown produce definite changes in the thyroid of dogs.

They emphasize, first of all, that increases in the functional activity of the gland are produced by these stimulating factors and that they are usually associated with definite morphologic changes. These stimuli, if intense, may cause desquamative changes within a few hours. Milder stimulation over a relatively longer period of time may, however, produce hyperplastic changes similar to those seen in exophthalmic goiter. Cessation of the stimulus leads to involution in a manner similar to that produced by iodine, but in either case replacement by fibrous tissue becomes a prominent feature of the process.

Repetition of this physiologic cycle of hyperplasia and involution led to the production of adenomas. It was found that fibrosis played the most important part in its development, for the location and occurrence of the nodules apparently depended on the amount and location of the scarring. Thus, the mechanism of their production was probably the encircling of a group of acini by fibrous tissue with subsequent cycles of hyperplasia and involution. The most frequent nodular changes were seen when a profuse ingrowth of scar tissue was achieved, as by the injection of a solution of trypsin into the inferior thyroid artery or by other methods. Some of these nodules resembled in great detail the so-called fetal adenoma. That such adenomas were in fact due to the experiment was shown by their absence in control biopsies of the gland in each case. Moreover, sections of the thyroid gland of several hundred normal dogs from the vicinity of St. Louis were examined over several years and in no instance was an adenoma encountered.

Clinical observations have, in general, confirmed this functional explanation of the origin of these nodules. Rienhoff and Lewis[2] have had the opportunity of comparing sections of human hyperplastic glands before and after iodine therapy and have noted the abundant development of the fibrosis and adenoma formation as a part of the involution from iodine. Both Dunhill[3] and Hertzler[4] have also shown that these so-called adenomas develop during the course of involution of an actively hyperplastic gland.

From these investigations it would seem that nothing as mysterious as embryonic rests needs to be invoked to explain nodular goiter. Their pathogenesis would seem to be merely part of the functional changes in the thyroid, physiologic, no doubt, though probably exerted only in response to various kinds of stimuli, themselves largely pathologic. Moreover, since their pathogenesis is similar they should present no greater problem in treatment than do ordinary cases of hyperplastic goiter, an idea which, in spite of some dispute, is beginning to be generally held on the basis of clinical study alone. The possible relationship of adenomas to the formation of carcinoma of the thyroid is not yet clearly understood.

DIET IN NEPHRITIS

The attitude of clinicians toward the problem of the protein intake in certain types of nephritis has been fundamentally altered in recent years. There was a time, not long ago, when the doctrine of "sparing the damaged kidneys" was rigorously applied in the dietary regimen of the patients. Realizing that the end-products of protein catabolism leave the body normally in the secretion of the kidneys, writers on clinical dietetics argued, with considerable logic, that a decrease in the intake of the food components involved ought to be beneficial to the nephritic patient. As a consequence, diets poor in protein were widely recommended. This attitude seemed to be further warranted by the allegation that high protein feeding is provocative of nephritis. Thus it has come about that many patients were experiencing a marked loss of protein not only because of the inadequate intake but also as a consequence of concomitant extensive albuminuria. Ultimately the plasma proteins may thus become depleted, with a resultant edema comparable to the now familiar nutritional edema.

The fact that nephritis is essentially a wasting disease is sometimes not fully appreciated, says Harrop,[1] particularly in patients who suffer from edema, which often gives them a fictitious appearance of good nutrition. He adds that persons with moderately advanced chronic nephritis are seldom overweight if the weight of the edema that may be present is disregarded. On the contrary, they are almost invariably underweight. That is why it becomes so important to supply an adequate caloric intake to spare nitrogenous metabolism as well as to furnish sufficient energy. Peters has accordingly pointed out that, if the caloric intake is deficient, more protein will be burned; if the protein intake sinks below a certain level, "all the calories in the world will not prevent wasting."

The danger of protein restriction—which has been termed a two-edged weapon—is becoming better recognized. As McLester[2] has remarked, protein destruction continues at all times, and the resulting nitrogenous waste products must pass through the kidneys, no matter how restricted the diet. Protein restriction cannot prevent this. Chronic nephritis often becomes a disease prolonged over months and years; hence the patient's strength must be conserved over long periods. The implications of this were stressed at the annual meeting of the Association of American Physicians,[3] held at Atlantic City. McCann and Kentmann of Rochester, N. Y., who have recently made observations on patients showing various manifestations of Bright's disease, have reached the conclusion that as much as 80 Gm. of protein may be given daily without adverse effects even when hemorrhagic symptoms occur. The urea clearance was, if anything, improved by reasonably liberal diets; and the hematuria was not aggravated. Van Slyke, of the Rockefeller Institute, likewise encouraged the use of generous protein feeding in hemorrhagic nephritis. As he expressed his views, at the present time there is no justification in keeping the proteins low in the diet of nephritic patients because of their nephritis. He remarked that often the most comfortable patients were "those who had the good fortune to escape being dieted." As a general rule a fairly liberal diet should be permitted, to maintain the patient's strength and vigor for the longest possible period. The body as a whole, as well as the kidneys, must be considered. So long as the food intake is kept within the digestive capacity of the patient and urea clearance is not aggravated, only good can result. There are many factors besides protein that need consideration in the management of nephritis.

Current Comment

GROWTH AFTER REPRODUCTION

Reproduction in the mammal does not necessarily represent a loss of material to the maternal organism; to the contrary, the observation is commonly made that after the completion of one or more reproductive cycles there is a tendency to an increase in body weight. An extensive study of the influence of reproduction on growth in the mouse has been made and the results have been recently reported by Agduhr.[1] Whereas the body weight of the virgin females of this species is less than that of the males at a given age, the size of the females increases with progressive pregnancies until it surpasses that of the male. This augmentation in body weight of the individual is due not only to the increase in adipose tissue but also to the growth of organs. The liver, lungs, kidneys and heart increased in size in the experimental group of females, which differed from the control animals only in having given birth to several litters of young. In the skeleton, reproduction brings about an increase in length and volume of bone in spite of the fact that there occurs a marked decalcification as a consequence of lactation. In this instance, again, there has been demonstrated a persistence of the growth of the organic portion of the bones under conditions that are unfavorable to the mineralization of this tissue. That the increase in size after repeated gravidities is probably influenced by the endocrine glands is suggested by the augmented size of the hypophysis, the thyroid and the parathyroids. One series of animals was given large amounts of viosterol each day. With this dietary change there was a decrease in the body weight of the virgin females, whereas reproduction increased the body weight in proportion to the number of pregnancies. In spite of the decalcifying action of large doses of viosterol, the bones increased in size with recurring reproductive cycles. These studies offer further cogent evidence of the pronounced amplifying effects of reproduction on the female body. One may view these changes as an overcompensation, a phenomenon more or less common throughout nature.

ALLERGY AND SPECIFIC HYPERSENSITIVENESS

Use determines the meaning of words. Through changing use, the meaning of a word may change. Regardless of etymology and of former meanings, the words anaphylaxis, allergy and, in their restricted or immunologic sense, hypersensitiveness, hypersusceptibility and idiosyncrasy are now used more and more as synonyms. Sensitization also is sometimes used in the same general sense. The author of a widely used textbook discusses all the phenomena indicated by these words under the general heading of hypersensitiveness. In recent articles by an investigator, sensitization is used as practically synonymous with anaphylaxis. The other day a popular magazine said that hay fever, asthma, hives and certain forms of food sensitivity are all forms of allergy. In the periodical literature and speech of the day, the words in question are used more or less interchangeably. Usage so far has not given to any of these words a definitely restricted or special meaning that has been accepted generally. Perhaps there is a tendency to use anaphylaxis in discussing the most acute and violent manifestations of specific hypersensitiveness, especially in animal experimentation. The general tendency to use these words as at least partial if not perfect synonyms and as conveying no distinctions of fundamental significance is in full harmony with present scientific conceptions of the essential nature of the phenomena described by the words. As research progresses, it becomes established more and more conclusively that in the various forms of hypersensitiveness in man there is concerned a mechanism of the same general type; namely, antigen-antibody reaction in a specifically sensitized or partially immunized organism. By the previous introduction of the antigen, or sensitization, the reactivity of the organism has been altered, and hence the appropriateness of the word allergy (changed reaction), the general use of which seems to be growing. It will be remembered that the unitary view of the mechanism of hypersensitiveness has been opposed because it was held that antigens are proteins and that hypersensitiveness may be caused by nonprotein substances. Now it is known not only that nonproteins, such as carbohydrates, may be antigenic but also that so-called simple chemicals may form antigenic combinations with proteins. Another obstacle to the unitary view has been the difficulty of explaining how the organism is sensitized in spontaneous hypersensitiveness, in the vast majority of the cases of which there seemed to be no obvious clue to any previous introduction of the specific antigen. But it is now known that various antigens easily may enter the body as such through the digestive and respiratory tracts and perhaps in other ways, in both health and disease, and there is no longer any difficulty in explaining natural sensitization. It has been found also that extremely minute quantities of antigen may sensitize. Perhaps the rôle of the hereditary factor in certain forms of hypersensitiveness consists in the development in the tissues of special tendencies to respond to antigens. Enough has been said to illustrate the drift both in scientific investigation and in the usage of names to accept the various manifestations of hypersensitiveness as based essentially on the same kind of immunologic mechanism.

OSTEITIS DEFORMANS

Since the first description of osteitis deformans by Sir James Paget of London, in 1876, more than five hundred cases have been recorded in medical literature. At present the x-rays afford almost the only means of detecting the disease in its early stages. Accordingly a recent writer has remarked that with the increasing use of roentgen examinations it appears reasonable that the incidence of the disease will probably be found to be still greater. Certain features of it indicate that there is doubtless a serious disturbance in the metabolism of some of the inorganic elements in the body. Several investigators have recorded a retention of calcium, magnesium and phosphorus and a loss of sulphur in cases of osteitis deformans; but such facts have not yet found widespread recognition in discussions of what is by no means a rare malady. In an investigation by Rabinowitch[1] at the Montreal General Hospital a new, carefully analyzed instance of the upset in the mineral metabolism has been brought to notice. Referring to the general behavior of the inorganic nutrients, Rabinowitch remarks that it would appear that the metabolism of sodium, potassium and chlorine differs from that of other elements; they not only play a small part in the formation of bone but also differ from the other elements in that the body appears to be able readily to adjust itself to any tendencies toward their deficiencies, though they may not always be interchangeable and, in some of their functions, may actually be antagonistic; the "law of the minimum," he adds, appears to be able to assert itself readily. In Rabinowitch's case the patient was practically in equilibrium with respect to sodium, potassium and chlorine. The lack of an effective defensive mechanism against loss of an insufficient supply of calcium, magnesium and phosphorus was shown by the positive balance exhibited for these elements. The basal metabolic rate was normal, as in other cases; hence the involvement of the thyroids in the etiology of osteitis deformans is probably excluded. Other aspects of the study tend to exclude the parathyroids as a cause. Hyposuprarenalism and hypersuprarenalism are also unlikely in the light of the clinical picture and laboratory data. Rabinowitch ventures the guess that osteitis deformans belongs to the so-called metabolic diseases rather than to the infectious disorders. The time is approaching when more sufficiently careful studies will help to solve the baffling problem of etiology.

Association News

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Talks

The American Medical Association broadcasts on Monday and Wednesday from 10:45 to 10:50 a. m., over Station WBBM (770 kilocycles, or 389.4 meters). The Columbia chain program has been discontinued for the present.

The subjects for the week are as follows:

September 12. Food and Food Advertising.
September 14. Cancer of the Bowel.

There is also a fifteen minute talk sponsored by the Association on Saturday morning from 10:45 to 11 over Station WBBM.

The subject for the week is as follows:

September 17. Children Who Might Live.

This schedule is based on Chicago daylight saving time, one hour faster than central standard time.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest: such as relate to society activities, new hospitals, education, public health, etc.)

ARKANSAS

Society News.—The county medical societies of Lawrence and Randolph were addressed in joint session in July by Drs. John C. Hughes, Hoxie, on treatment of diabetes, and Horace R. McCarroll, typhoid.——Dr. Sidney J. Wolfermann, Fort Smith, addressed the Crawford Medical Society in Van Buren, July 26, on the colon.

CALIFORNIA

Child Development Program.—The first county-wide program in child development work in the state, particularly adapted to farm children, will be projected in Santa Cruz County in a series of meetings, beginning September 12, according to a recent announcement. The general purpose of the conferences is to lay plans for the coordination of all the work in the county pertaining to child development and parent education, it was said. Exhibits and demonstrations will be features of the meetings, at which the chairman of the farm home department, College of Agriculture, University of California, will preside.

Changes in Health Officers.—Dr. Frank M. Lawson, Willows, has been appointed health officer of Glenn County, succeeding the late Dr. Samuel Iglick. Dr. Thomas H. Brown succeeds Dr. Iglick as health officer of Orland. Dr. David M. Kindopp replaces the late Dr. Charles J. Durand as health officer of Colfax. Dr. Kindopp is also health officer of Placer County. Dr. Louis L. Robinson has been appointed health officer of the recently incorporated city of Fairfax. The city of Delano, in Kern County, has transferred its public health work to the Kern County Health Department, of which Dr. Joseph Smith is health officer. Mr. A. Ackerman served as health officer of Delano for many years.

License Revoked—Physicians Placed on Probation.—The license of Dr. Robert H. MacLauchlan, San Francisco, was revoked, July 14, by the state board of medical examiners for violation of probation. Dr. MacLauchlan was placed on probation, July 9, 1931, when his license was restored; it had been suspended, Oct. 30, 1930, for aiding and abetting an unlicensed practitioner (The Journal, Aug. 8, 1931, p. 395). The following physicians were placed on probation for the periods indicated, after hearings based on record of conviction or plea of guilty in federal court in connection with veterans' bureau claims: Isaac Alexander, Oakland, five years; Reo B. Armitstead, Ventura, one year; William E. Glaeser, San Francisco, one year; Edward Purcell, one year; Fred H. Van Tassell, five years, Oakland, and John R. Vasko, Alameda, three years. Dr. Filiberto A. Bonaventura, Santa Rosa, was placed on probation for three years, without narcotic privileges, for narcotic violation.

FLORIDA

Mosquito Survey.—What is described as the first investigation of its kind in Florida was begun, August 22, when a group of public health officials started a survey into the mosquito-malaria situation in the state, newspapers reported. The survey began at Tampa, and will continue south to Fort Myers, across the lower Everglades to Miami, then north to West Palm Beach, again into the Everglades area and north to Orlando. Included in the group making the survey are Dr. Mark F. Boyd, Tallahassee, of the Rockefeller Foundation; Dr. Thomas H. D. Griffitts, Albany, Ga., of the U. S. Public Health Service, and Dr. Henry Hanson, state health officer.

GEORGIA

Hospital News.—The Georgia Hospital Association was reorganized at a meeting in Atlanta, July 28. Miss Annie B. Feebeck was elected president, and Mr. George R. Burt, executive secretary.

Society News.—Dr. Henry R. Donaldson addressed the Fulton County Medical Society, Atlanta, September 1, on "The Functionless Gallbladder." Dr. Charles B. Upshaw gave a clinical talk on "Conservative Treatment of Eclampsia."——Dr. Richard B. Wilson, Atlanta, presented a paper on syphilis of the nervous system at the meeting of the society, August 18. ——Dr. Wilborn A. Upchurch, Atlanta, recently addressed the Eighth District Medical Society at Madison, on prostatic resection.

IDAHO

Hospital News.—A twenty-bed hospital was recently opened at St. Anthony, by Dr. Thomas A. Ellison.——Dr. William E. Waldrop, Parma, has been appointed commandant of the Idaho Soldiers' Home, Boise.

State Medical Meeting at Pocatello.—The fortieth annual session of the Idaho State Medical Association will be held at Pocatello, September 16-17, under the presidency of Dr. Joseph Nelson Davis, Kimberly. The following speakers will be included on the program:

Dr. Caroline McGill, Butte, Mont., "Menorrhagia" and "Tissue Diagnosis and the General Surgeon."
Dr. William Dock, San Francisco, "Treatment of Cardiac Irregularity" and "Suggestions as to Cause and Treatment of Chronic Arthritis."
Dr. Frederick L. Reichert, San Francisco, "Interruption of Sympathetic Pathways for Relief of Pain in the Extremities" and "Neuralgia of Certain Sensory and Sympathetic Nerves."
Dr. Platt W. Covington of the Rockefeller Foundation, Salt Lake City, Utah, "State Health Departments."
Dr. Lyle B. Kingery, Portland, Ore., "Ringworm Infection, Clinical Types, Diagnosis and Treatment."
Dr. Dorrell G. Dickerson, Seattle, "Migraine" and "Brain Abscess."
Dr. Alfred W. Adson, Rochester, Minn., "Spinal Cord Tumors, Diagnosis and Treatment."
Dr. Albert Mathieu, Portland, Ore., "Induction of Labor"; "Diet in Its Relation to the Teeth of the Pregnant Woman and Her Offspring."
Dr. Thomas Jones, Cleveland, cancer of the uterus, breast and rectum, discussed separately.
Dr. John M. Flude, Los Angeles, "The Cancer Problem and the Individual Physician."

INDIANA

Personal.—Dr. William Franklin Hughes, Indianapolis, has been appointed head of the department of ophthalmology at Indiana University School of Medicine to succeed the late Dr. Albert E. Bulson. He has been a member of the school faculty since 1903.

License Revoked.—The license of Dr. David B. Harvey, Marion, was revoked by the Indiana State Board of Medical Registration and Examination at a meeting, July 12. Dr. Harvey is serving a life sentence in the Indiana State Prison, having been convicted of murder.

IOWA

Hospital News.—The new Lutheran Hospital, Fort Dodge, erected at a cost of $100,000, was opened recently. It has a capacity of 110 beds.

Personal.—Dr. Herbert R. Sugg, Clinton, has been appointed a member of the state board of health, succeeding the late Dr. Cassius T. Lesan, Mount Ayr.

Society News.—Dr. Walter D. Abbott, Des Moines, among others, addressed the Dallas-Guthrie Medical Society, July 21, on "Injuries to the Brain, Including Traumatic Epilepsy."

KANSAS

Personal.—Dr. Clarence R. Hepler, Columbus, health officer of Cherokee County, has been appointed health officer of Sedgwick County, succeeding the late Dr. Menno H. Hostetler, effective July 1. He has held the former position for twenty-five years.

KENTUCKY

Society News.—At a meeting of the Third District Medical Society in Bowling Green, August 17, speakers were Drs. John H. Blackburn, Bowling Green, on septicemia following appendicitis; Clifton G. Follis, Glasgow, the cystic ovary; Worcester A. Bryan, Nashville, Tenn., enterospasm, and Emmet F. Horine, Louisville, hypertensive heart disease.——At a meeting of the Cave Area Public Health Association at Columbia, August 16, speakers included Drs. Arthur T. McCormack, state health officer, on "The Value of a Full Time Health Department"; Lucius E. Smith, "Newer Phases of Tuberculosis" and Philip F. Barbour, president-elect of the Kentucky State Medical Association, all of Louisville. Drs. McCormack and Smith addressed a public mass meeting in the evening on rural health problems and control of tuberculosis, respectively.

State Medical Meeting.—The eighty-second annual meeting of the Kentucky State Medical Association will be held at the Brown Hotel, Louisville, October 3-6, under the presidency of Dr. Philip F. Barbour, Louisville. Dr. John Lovett Morse, Boston, will deliver the annual oration at a public meeting, Tuesday evening. Dr. Roy Glenwood Spurling, Louisville, will give the oration in surgery on "The Epileptic Problem" and Dr. Charles N. Kavanaugh, Lexington, the oration in medicine, on "Chronic Hypochromic Anemia." The program announces symposiums on anemias and on obstetrics. Among the physicians who will present papers are Drs. Carlisle R. Petty, Lynch, "Treatment of Compound Fractures"; Ernest Owsley Grant, Louisville, "Relief of Prostatic Obstruction Through the Urethra," and William Clark Bailey, Harlan, "Diagnosis and Treatment of Empyema." The last day's program will be presented by members of the faculty of the University of Louisville School of Medicine, among whom will be Drs. Robert L. Woodard, on "Radical Treatment of Joint Tuberculosis"; Edward Speidel, "Clinical Progress in Obstetrics"; Charles W. Hibbitt, "Varicose Veins of the Broad Ligament as Cause of Pelvic Discomfort"; Walter Dean, "Prognosis of Paranasal Sinus Disease," and Bernard Asman, "Anorectal Disease." At the annual banquet at the Brown Hotel, Wednesday, October 5, speakers will be Ira V. Hiscock, C.P.H., associate professor of public health, Yale University School of Medicine, New Haven; Mrs. Walter Jackson Freeman, Philadelphia, president of the Woman's Auxiliary, American Medical Association, and Mrs. Charles E. Oates, North Little Rock, Ark., president of the Woman's Auxiliary, Southern Medical Association.

MAINE

Society News.—Dr. Charles Herbert Best, professor of physiology and assistant professor of hygiene and preventive medicine, University of Toronto Faculty of Medicine, addressed a recent meeting of the Washington County Medical Society at Calais. Papers were also presented at this session by Drs. Ernest H. Bennet, Lubec, and Clifford D. Harvey, Boston, on "Early Diagnosis and Prevention of Cancer" and "Ulcers of the Duodenum and Stomach," respectively.

MARYLAND

Dr. Williams Appointed Health Commissioner.—The appointment of Dr. Huntington Williams as commissioner of health of Baltimore to succeed the late Dr. C. Hampson Jones will take place in October, it is announced. In 1931, Dr. Williams resigned as secretary of the New York State Department of Health, Albany, to become director of health of Baltimore, a new position created to increase efficiency of the city health department (The Journal, Aug. 22, 1931, p. 545). He had been connected with the New York department since 1922. Since Dr. Jones's death, April 11, Dr. Williams has been acting commissioner of health.

Dr. Mustard to Head New Public Health District.—Dr. Harry Stoll Mustard, director of health education and of child hygiene and public health nursing, Tennessee state department of health, has been selected to take charge of the new public health district which was recently created in Baltimore. Dr. Mustard, who was formerly connected with the U. S. Public Health Service, will also be an assistant professor in the School of Hygiene and Public Health of Johns Hopkins University. He went to Tennessee in 1924 as director of the child health demonstration of the Commonwealth Fund at Murfreesboro. Recently he has been instructor in public health and preventive medicine at Vanderbilt University School of Medicine, Nashville. The health district will be placed in operation, September 15, it was announced. With the creation of this district the training of public health workers has bee made possible by a grant of about $25,000 for two or m there is no longer any difficulty in explaining natural sensitization. It has been found also that extremely minute quantities of antigen may sensitize. Perhaps the rôle of the hereditary factor in certain forms of hypersensitiveness consists in the development in the tissues of special tendencies to respond to antigens. Enough has been said to illustrate the drift both in scientific investigation and in the usage of names to accept the various manifestations of hypersensitiveness as based essentially on the same kind of immunologic mechanism.

OSTEITIS DEFORMANS

Since the first description of osteitis deformans by Sir James Paget of London, in 1876, more than five hundred cases have been recorded in medical literature. At present the x-rays afford almost the only means of detecting the disease in its early stages. Accordingly a recent writer has remarked that with the increasing use of roentgen examinations it appears reasonable that the incidence of the disease will probably be found to be still greater. Certain features of it indicate that there is doubtless a serious disturbance in the metabolism of some of the inorganic elements in the body. Several investigators have recorded a retention of calcium, magnesium and phosphorus and a loss of sulphur in cases of osteitis deformans; but such facts have not yet found widespread recognition in discussions of what is by no means a rare malady. In an investigation by Rabinowitch[1] at the Montreal General Hospital a new, carefully analyzed instance of the upset in the mineral metabolism has been brought to notice. Referring to the general behavior of the inorganic nutrients, Rabinowitch remarks that it would appear that the metabolism of sodium, potassium and chlorine differs from that of other elements; they not only play a small part in the formation of bone but also differ from the other elements in that the body appears to be able readily to adjust itself to any tendencies toward their deficiencies, though they may not always be interchangeable and, in some of their functions, may actually be antagonistic; the "law of the minimum," he adds, appears to be able to assert itself readily. In Rabinowitch's case the patient was practically in equilibrium with respect to sodium, potassium and chlorine. The lack of an effective defensive mechanism against loss of an insufficient supply of calcium, magnesium and phosphorus was shown by the positive balance exhibited for these elements. The basal metabolic rate was normal, as in other cases; hence the involvement of the thyroids in the etiology of osteitis deformans is probably excluded. Other aspects of the study tend to exclude the parathyroids as a cause. Hyposuprarenalism and hypersuprarenalism are also unlikely in the light of the clinical picture and laboratory data. Rabinowitch ventures the guess that osteitis deformans belongs to the so-called metabolic diseases rather than to the infectious disorders. The time is approaching when more sufficiently careful studies will help to solve the baffling problem of etiology.

---

Association News

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Talks

The American Medical Association broadcasts on Monday and Wednesday from 10:45 to 10:50 a. m., over Station WBBM (770 kilocycles, or 389.4 meters). The Columbia chain program has been discontinued for the present.

The subjects for the week are as follows:

September 12. Food and Food Advertising.
September 14. Cancer of the Bowel.

There is also a fifteen minute talk sponsored by the Association on Saturday morning from 10:45 to 11 over Station WBBM.

The subject for the week is as follows:

September 17. Children Who Might Live.

This schedule is based on Chicago daylight saving time, one hour faster than central standard time.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest: such as relate to society activities, new hospitals, education, public health, etc.)

ARKANSAS

Society News.—The county medical societies of Lawrence and Randolph were addressed in joint session in July by Drs. John C. Hughes, Hoxie, on treatment of diabetes, and Horace R. McCarroll, typhoid.——Dr. Sidney J. Wolfermann, Fort Smith, addressed the Crawford Medical Society in Van Buren, July 26, on the colon.

CALIFORNIA

Child Development Program.—The first county-wide program in child development work in the state, particularly adapted to farm children, will be projected in Santa Cruz County in a series of meetings, beginning September 12, according to a recent announcement. The general purpose of the conferences is to lay plans for the coordination of all the work in the county pertaining to child development and parent education, it was said. Exhibits and demonstrations will be features of the meetings, at which the chairman of the farm home department, College of Agriculture, University of California, will preside.

Changes in Health Officers.—Dr. Frank M. Lawson, Willows, has been appointed health officer of Glenn County, succeeding the late Dr. Samuel Iglick. Dr. Thomas H. Brown succeeds Dr. Iglick as health officer of Orland. Dr. David M. Kindopp replaces the late Dr. Charles J. Durand as health officer of Colfax. Dr. Kindopp is also health officer of Placer County. Dr. Louis L. Robinson has been appointed health officer of the recently incorporated city of Fairfax. The city of Delano, in Kern County, has transferred its public health work to the Kern County Health Department, of which Dr. Joseph Smith is health officer. Mr. A. Ackerman served as health officer of Delano for many years.

License Revoked—Physicians Placed on Probation.—The license of Dr. Robert H. MacLauchlan, San Francisco, was revoked, July 14, by the state board of medical examiners for violation of probation. Dr. MacLauchlan was placed on probation, July 9, 1931, when his license was restored; it had been suspended, Oct. 30, 1930, for aiding and abetting an unlicensed practitioner (The Journal, Aug. 8, 1931, p. 395). The following physicians were placed on probation for the periods indicated, after hearings based on record of conviction or plea of guilty in federal court in connection with veterans' bureau claims: Isaac Alexander, Oakland, five years; Reo B. Armitstead, Ventura, one year; William E. Glaeser, San Francisco, one year; Edward Purcell, one year; Fred H. Van Tassell, five years, Oakland, and John R. Vasko, Alameda, three years. Dr. Hiliberto A. Bonaventura, Santa Rosa, was placed on probation for three years, without narcotic privileges, for narcotic violation.

FLORIDA

Mosquito Survey.—What is described as the first investigation of its kind in Florida was begun, August 22, when a group of public health officials started a survey into the mosquito-malaria situation in the state, newspapers reported. The survey began at Tampa, and will continue south to Fort Myers, across the lower Everglades to Miami, then north to West Palm Beach, again into the Everglades area and north to Orlando. Included in the group making the survey are Dr. Mark F. Boyd, Tallahassee, of the Rockefeller Foundation; Dr. Thomas H. D. Griffitts, Albany, Ga., of the U. S. Public Health Service, and Dr. Henry Hanson, state health officer.

GEORGIA

Hospital News.—The Georgia Hospital Association was reorganized at a meeting in Atlanta, July 28. Miss Annie B. Feebeck was elected president, and Mr. George R. Burt, executive secretary.

Society News.—Dr. Henry R. Donaldson addressed the Fulton County Medical Society, Atlanta, September 1, on "The Functionless Gallbladder." Dr. Charles B. Upshaw gave a clinical talk on "Conservative Treatment of Eclampsia."——Dr. Richard B. Wilson, Atlanta, presented a paper on syphilis of the nervous system at the meeting of the society, August 18.——Dr. Wilborn A. Upchurch, Atlanta, recently addressed the Eighth District Medical Society at Madison, on prostatic resection.

IDAHO

Hospital News.—A twenty-bed hospital was recently opened at St. Anthony, by Dr. Thomas A. Ellison.——Dr. William E. Waldrop, Parma, has been appointed commandant of the Idaho Soldiers' Home, Boise.

State Medical Meeting at Pocatello.—The fortieth annual session of the Idaho State Medical Association will be held at Pocatello, September 16-17, under the presidency of Dr. Joseph Nelson Davis, Kimberly. The following speakers will be included on the program:

Dr. Caroline McGill, Butte, Mont., "Menorrhagia" and "Tissue Diagnosis and the General Surgeon."
Dr. William Dock, San Francisco, "Treatment of Cardiac Irregularity" Cause and Treatment of Chronic Arthritis."
Dı San Francisco, "Interruption of Sympathetic Pain in the Extremities" and "Neuralgia of Certain Sensory and Sympathetic Nerves."
Dr. Platt W. Covington of the Rockefeller Foundation, Salt Lake City, Utah, "State Health Departments."
Dr. Lyle B. Kingery, Portland, Ore., "Ringworm Infection, Clinical Types, Diagnosis and Treatment."
Dr. Dorrell G. Dickerson, Seattle, "Migraine" and "Brain Abscess."
Dr. Alfred W. Adson, Rochester, Minn., "Spinal Cord Tumors, Diagnosis and Treatment."
Dr. Albert Mathieu, Portland, Ore., "Induction of Labor"; "Diet in Its Relation to the Teeth of the Pregnant Woman and Her Offspring."
Dr. Thomas Jones, Cleveland, cancer of the uterus, breast and rectum, discussed separately.
Dr. John M. Flude, Los Angeles, "The Cancer Problem and the Individual Physician."

INDIANA

Personal.—Dr. William Franklin Hughes, Indianapolis, has been appointed head of the department of ophthalmology at Indiana University School of Medicine to succeed the late Dr. Albert E. Bulson. He has been a member of the school faculty since 1903.

License Revoked.—The license of Dr. David B. Harvey, Marion, was revoked by the Indiana State Board of Medical Registration and Examination at a meeting, July 12. Dr. Harvey is serving a life sentence in the Indiana State Prison, having been convicted of murder.

IOWA

Hospital News.—The new Lutheran Hospital, Fort Dodge, erected at a cost of $100,000, was opened recently. It has a capacity of 110 beds.

Personal.—Dr. Herbert R. Sugg, Clinton, has been appointed a member of the state board of health, succeeding the late Dr. Cassius T. Lesan, Mount Ayr.

Society News.—Dr. Walter D. Abbott, Des Moines, among others, addressed the Dallas-Guthrie Medical Society, July 21, on "Injuries to the Brain, Including Traumatic Epilepsy."

KANSAS

Personal.—Dr. Clarence R. Hepler, Columbus, health officer of Cherokee County, has been appointed health officer of Sedgwick County, succeeding the late Dr. Menno H. Hostetler, effective July 1. He has held the former position for twenty-five years.

KENTUCKY

Society News.—At a meeting of the Third District Medical Society in Bowling Green, August 17, speakers were Drs. John H. Blackburn, Bowling Green, on septicemia following appendicitis; Clifton G. Follis, Glasgow, the cystic ovary; Worcester A. Bryan, Nashville, Tenn., enterospasm, and Emmet F. Horine, Louisville, hypertensive heart disease.——At a meeting of the Cave Area Public Health Association at Columbia, August 16, speakers included Drs. Arthur T. McCormack, state health officer, on "The Value of a Full Time Health Department"; Lucius E. Smith, "Newer Phases of Tuberculosis" and Philip F. Barbour, president-elect of the Kentucky State Medical Association, all of Louisville. Drs. McCormack and Smith addressed a public mass meeting in the evening on rural health problems and control of tuberculosis, respectively.

State Medical Meeting.—The eighty-second annual meeting of the Kentucky State Medical Association will be held at the Brown Hotel, Louisville, October 3-6, under the presidency of Dr. Philip F. Barbour, Louisville. Dr. John Lovett Morse, Boston, will deliver the annual oration at a public meeting, Tuesday evening. Dr. Roy Glenwood Spurling, Louisville, will give the oration in surgery on "The Epileptic Problem" and Dr. Charles N. Kavanaugh, Lexington, the oration in medicine, on "Chronic Hypochromic Anemia." The program announces symposiums on anemias and on obstetrics. Among the physicians who will present papers are Drs. Carlisle R. Petty, Lynch, "Treatment of Compound Fractures"; Ernest Owsley Grant, Louisville, "Relief of Prostatic Obstruction Through the Urethra," and William Clark Bailey, Harlan, "Diagnosis and Treatment of Empyema." The last day's program will be presented by members of the faculty of the University of Louisville School of Medicine, among whom will be Drs. Robert L. Woodard, on "Radical Treatment of Joint Tuberculosis"; Edward Speidel, "Clinical Progress in Obstetrics"; Charles W. Hibbitt, "Varicose Veins of the Broad Ligament as Cause of Pelvic Discomfort"; Walter Dean, "Prognosis of Paranasal Sinus Disease," and Bernard Asman, "Anorectal Disease." At the annual banquet at the Brown Hotel, Wednesday, October 5, speakers will be Ira V. Hiscock, C.P.H., associate professor of public health, Yale University School of Medicine, New Haven; Mrs. Walter Jackson Freeman, Philadelphia, president of the Woman's Auxiliary, American Medical Association, and Mrs. Charles E. Oates, North Little Rock, Ark., president of the Woman's Auxiliary, Southern Medical Association.

MAINE

Society News.—Dr. Charles Herbert Best, professor of physiology and assistant professor of hygiene and preventive medicine, University of Toronto Faculty of Medicine, addressed a recent meeting of the Washington County Medical Society at Calais. Papers were also presented at this session by Drs. Ernest H. Bennet, Lubec, and Clifford D. Harvey, Boston, on "Early Diagnosis and Prevention of Cancer" and "Ulcers of the Duodenum and Stomach," respectively.

MARYLAND

Dr. Williams Appointed Health Commissioner.—The appointment of Dr. Huntington Williams as commissioner of health of Baltimore to succeed the late Dr. C. Hampson Jones will take place in October, it is announced. In 1931, Dr. Williams resigned as secretary of the New York State Department of Health, Albany, to become director of health of Baltimore, a new position created to increase efficiency of the city health department (The Journal, Aug. 22, 1931, p. 545). He had been connected with the New York department since 1922. Since Dr. Jones's death, April 11, Dr. Williams has been acting commissioner of health.

Dr. Mustard to Head New Public Health District.—Dr. Harry Stoll Mustard, director of health education and of child hygiene and public health nursing, Tennessee state department of health, has been selected to take charge of the new public health district which was recently created in Baltimore. Dr. Mustard, who was formerly connected with the U. S. Public Health Service, will also be an assistant professor in the School of Hygiene and Public Health of Johns Hopkins University. He went to Tennessee in 1924 as director of the child health demonstration of the Commonwealth Fund at Murfreesboro. Recently he has been instructor in public health and preventive medicine at Vanderbilt University School of Medicine, Nashville. The health district will be placed in operation, September 15, it was announced. With the creation of this district the training of public health workers has been made possible by a grant of about $25,000 for two or more years from the Rockefeller Foundation, through the school of hygiene and public health. No radical departures from present public health practices are contemplated under the plan, nor is it proposed to make the residents of the sixth and seventh wards of Baltimore, which constitute the district, the subject of medical experimentation in the public health field, it was stated. The establishment of the district was a recommendation of Dr. Joseph Mountin in his report on the public health survey of Baltimore.

MICHIGAN

Personal.—Malcolm H. Soule, Sc.D., professor of bacteriology, University of Michigan Medical School, Ann Arbor, will present a paper on "Microbic Dissociation" at the meeting of the International Society for Microbiology in Milan, Italy, in October.

Hospital News.—A new receiving hospital for the Newberry State Hospital, Newberry, to cost $364,000, has been authorized. The building is expected to accommodate 100 patients.——Two buildings, constituting the second unit of the Ypsilanti State Hospital, were formally dedicated, July 27, by Governor Brucker. It is expected that they will give an added capacity of 450 beds to the state institution.

Society News.—Dr. J. Duane Miller, Grand Rapids, read a paper on "Modern Viewpoints on the Etiology and Treatment of Female Disease" before the Berrien County Medical Society, August 24. Dr. Alexander M. Campbell, Grand Rapids, was to have given the paper but was unable to attend.——Dr. Roscoe L. Sensenech, South Bend, Ind., addressed the Berrien and Cass county medical societies, July 28, on "A Review of Gastro-Intestinal Symptomatology—Diagnosis and Treatment."

Peninsula Society Meeting.—Dr. Emil H. Webster, Sault Sainte Marie, was elected president of the Upper Peninsula Medical Society at its meeting in Sault Sainte Marie, August 11-12. The society will meet in Escanaba in 1933. Among the speakers were Drs. Edgar V. Allen, Rochester, Minn., on "Thrombo-Angiitis Obliterans and Arteriovenous Fistula"; George H. Gardner, Chicago, "Some Newer Phases of Gynecology"; Louis J. Hirschman, Detroit, "The Anal Canal as a Focus of Infection." Dr. Carl F. Moll, Flint, president, Michigan State Medical Society; Dr. James Milton Robb, Detroit, president-elect, and Dr. Clyde C. Slemons, state health commissioner, among others, made five-minute talks at the annual banquet, at which former Governor Chase S. Osborn, Sault Sainte Marie, made the principal address. Dr. Wyllys A. Manthei, Lake Linden, retiring president of the society, was toastmaster.

MISSISSIPPI

Cooperative Health Work Inspected.—Dr. Marta Robert, San Juan, P. R., chief division of child hygiene, Puerto Rico Department of Health, spent a week in Mississippi in July observing and studying the maternal and infant hygiene activities of the state board of health. In 1931, the Commonwealth Fund selected Mississippi for cooperative health work and established full time health units in Pike and Lauderdale counties. Other recent visitors to observe the health program of Mississippi were Dr. Percy L. Querens, Tulane University Graduate School of Medicine, New Orleans; Dr. Taliaferro Clark, U. S. Public Health Service, Washington, D. C.; Dr. C. J. Hollister, D.D.S., department of health of Harrisburg, Pa., and Carl E. Buck, Dr. P.H., American Public Health Association, New York.

NEBRASKA

Acting Dean Appointed.—The Rev. John J. McInerney, S. J., regent of Creighton University School of Medicine, Omaha, will serve as acting dean of the school, assisted by Drs. Bryan M. Riley, professor of medicine, and Herbert F. Gerald, professor of pharmacology, it has been announced. Dr. Herman von W. Schulte, dean since 1918, died July 13. Dr. Riley succeeds Dr. Schulte as chairman of the administrative board.

NEW JERSEY

Society News.—Dr. Jesse O. Arnold, Philadelphia, addressed the Cumberland County Medical Society, July 12, at Jericho, on treatment of eclampsia.——Dr. Edgar Burke, Jersey City, discussed "Unusual Abdominal Operations" before the Union County Medical Society, meeting at Summit, July 13.——The state department of health has suspended the publication of its bulletin, *Public Health News*, for an indefinite period. A mimeographed news letter will take its place.

Illegal Practitioners Prosecuted.—Sixteen persons have been convicted of practicing medicine without a license within recent months, according to a report of the activities of the New Jersey state board of medical examiners. Among them were:

Alexander Zabo, who conducted an herb steam bath establishment in New Brunswick.

Charles B. Richardson, a licensed osteopath who exceeded his osteopathic license by giving electrical treatments.

Yuk Sun Chin, a Chinese herb doctor of Hoboken.

John S. Hussa, an electrotherapist of Asbury Park.

Samuel A. Weinraub, Jamesburg; Benjamin Faunce, Riverside; Isadore M. Greenburg, Newark, all druggists.

NEW YORK

Personal.—Dr. Mary C. Conant is reported to have resigned from the staff of the Newark State School, Newark, after twelve years of service there and nineteen in the service of New York State.——Dr. Walter A. Leonard, Cambridge, has been appointed a member of the Public Health Council by Governor Roosevelt. He succeeds Dr. Stanton P. Hull, Troy.

Foreign Medical Schools Recognized.—The New York State Department of Education has listed for the guidance of students wishing to study medicine abroad the medical schools that meet its requirements for licensing examinations. The approved schools in Canada are those of Dalhousie University, Halifax; McGill University, Montreal; Queens University, Kingston, Ont.; Laval University, Quebec, and the universities of Toronto, Alberta (at Edmonton) and Western Ontario (at London). Medical faculties of all governmental universities in Austria, Germany, Holland, Hungary and the Scandinavian countries and all those that are part of English, Irish and Scottish universities are on the list. In order that courses in medicine in these foreign schools may be accepted, it is necessary that the students take two years of premedical work, including the required sciences, before beginning professional study.

Minimum Death Rates.—The death rate for tuberculosis in New York for June was the lowest ever recorded for the month, 64 per hundred thousand of population, according to *Health News*. Infant mortality (48) was the lowest ever recorded for June with the exception of 1931, when the rate was 44. The death rate from diarrhea and enteritis in children under 2 years of age was 4.6, the lowest ever recorded in any month and one fifth of the rate ten years ago (22.3). Maternal mortality was the lowest for June in six years (46.4 per 10,000 total births). Death rates from measles, whooping cough and diphtheria were low, but the mortality from scarlet fever was the highest in June in ten years. The death rate from automobile accidents (69.8) was also a record, the lowest for any June since 1907. On the other hand, death rates from cancer and diabetes were the highest ever recorded with the exception of June, 1930, and mortality from heart disease was the highest except for June, 1928. The suicide rate (21.6) was the highest ever recorded for June.

New York City

Friday Afternoon Lectures.—The fall series of Friday afternoon lectures for the Medical Society of the County of Kings, Brooklyn, has been arranged as follows:

October 7, Dr. Harrison S. Martland, Newark, N. J., "Interesting Pathological Cases from a Diagnostic Viewpoint."

October 14, Dr. Fred Wise, "Common Infections of the Hair and Hair Follicle."

October 21, Dr. Reginald Fitz, Boston, "Treatment of Diabetes: Its Importance, Insulin, Coma and Common Complications and Their Treatment."

October 28, Dr. Russell L. Haden, Cleveland, "Purpura and Pathological Hemorrhage."

November 4, Dr. Edward M. Livingston, "Diagnosis of Diseases of the Abdomen."

November 11, Dr. Morris Edward Davis, Chicago, "Toxemias of Pregnancy."

November 18, Dr. Milton G. Wasch, Brooklyn, "Roentgen Therapy: Its Modern Application in Benign and Malignant Diseases, Indications and Contraindications."

December 2, Dr. Smith Ely Jelliffe, "Value of Psychoanalytic Understanding in Medicine."

December 9, Dr. Albert D. Kaiser, Rochester, "When Are Children's Tonsils Abnormal? How Should They Be Treated?"

December 16, Dr. Benjamin Kramer, "Prophylaxis and Therapy of the Most Important Infectious Diseases of Children."

University News.—Dr. Harold J. Stewart has been appointed associate professor of medicine at Cornell University Medical College and attending physician at New York Hospital. Dr. James Lionel Alloway has been appointed assistant professor of bacteriology in the medical college.——The New York Post-Graduate Medical School of Columbia University will offer to medical graduates a week's intensive course in the theory and practice of traumatic surgery, October 10-15, under the direction of Dr. John J. Moorhead.

Annual Fracture Demonstrations.—The New York and Brooklyn Regional Fracture Committee of the American College of Surgeons will give its annual course on fracture treatment, October 31 to November 5. Clinics will be held at eight leading hospitals. Lectures will cover diagnosis and treatment of all types of injuries to the bone, with demonstrations of actual cases. There will also be symposiums on bone repair, operative treatment of fractures, delayed union and care of compound fractures. Information may be obtained from Dr. Fenwick Beekman, 121 East Sixtieth Street, New York, secretary of the committee.

OHIO

Personal. — Dr. Robert H. Grube, Xenia, will retire as health officer of Greene County, October 1, it is reported, after several years' service. He is at present president of the Greene County Medical Society.——Dr. Elias Dalton Peelle, Wilmington, has been appointed head football coach at Wilmington College for a period of one year.

Hospital News.—A new building for the Bucyrus City Hospital was dedicated, July 11; it has accommodations for thirty-seven patients. The old hospital will be sold and removed from the grounds.——The cornerstone of Lima Memorial Hospital, recently completed at a cost of $500,000, was laid, August 22, with ceremonies conducted by Masons of Lima. The new building replaces the old Lima Hospital.——The nurses' training school at the Home and Hospital, Findlay, will be suspended, October 1, on account of financial conditions, it is reported.

Society News.—At a meeting of the Adams County Medical Society, West Union, August 17, speakers were Drs. Frederick C. Leeds, Winchester, on hemorrhagic pancreatitis; William G. Phillips, Maysville, Ky., "Preoperative and Postoperative Care of the Surgical Patient" and Martin L. Purdin, West Union, gastro-enteritis.——Dr. Robert Conard, Wilmington, addressed the Clinton County Medical Society, August 2, on examination of the lungs.——Dr. Townsend H. Dickinson, Dayton, addressed the Greene County Medical Society, Xenia, August 4, on "Intestinal Infection in Children."

PENNSYLVANIA

State Medical Meeting in Pittsburgh.—The eighty-second annual session of the Medical Society of the State of Pennsylvania will be held in Pittsburgh, October 3-6, under the presidency of Dr. Charles Falkowsky, Jr., Scranton. Guest speakers announced include:

Dr. Frank H. Lahey, Boston, on "Changing Concepts in Treatment of Peptic Ulcer."
Dr. Russell L. Cecil, New York, "Laboratory Methods in the Diagnosis and Treatment of Arthritis."
Dr. Thomas M. Rivers, New York, "Diseases Due to the Filtrable Viruses."
Dr. John F. Erdmann, New York, "Recognition and Treatment of Postoperative Complications"
Dr. George E. Brown, Rochester, Minn., "Diseases of the Peripheral Blood Vessels."
Dr. William Darrach, New York, "Conditions Causing Delay or Complications in the Healing of Fractures."
Dr. Bernard Samuels, New York, "Intra-Ocular Tumors."
Dr. Samuel J. Kopetzky, New York, "Otitic Complications as They Occur in Everyday Otology."
Dr. Jesse R. Gerstley, Chicago, "Infant Nutrition."
Dr. Roger H. Dennett, New York, "Nirvanol Treatment of Chorea."
Dr. Oliver S. Ormsby, Chicago, "Neurodermatitis."
Dr. Joseph F. McCarthy, New York, "Progress in Prostatic Surgery."

Dr. Albert H. Freiberg, Cincinnati, will give an address at the opening session on "Economic Implications of Modern Medicine," and Dr. Falkowsky will give the presidential address following his installation. There will be symposiums on cardiovascular disease, head injuries, surgery of the colon, disease of the thyroid and tumors of the kidney.

Philadelphia

Personal.—Dr. Edward Quin Thornton, associate professor of materia medica at Jefferson Medical College, has been appointed Sutherland M. Prevost professor of therapeutics, to succeed the late Dr. Elmer H. Funk.——The University of Vienna has bestowed on Dr. George W. Mackenzie a gold honor medal with a diploma of the university in recognition of his work in diseases of the eye, ear, nose and throat.

Director Appointed for Cox Institute.—Dr. Cyril N. H. Long, assistant professor of medical research, McGill University Faculty of Medicine, Montreal, has been appointed director of the George S. Cox Medical Institute for research in diabetes at the University of Pennsylvania Hospital. Dr. Long, who has been engaged in investigations of diabetes and diseases of metabolism at McGill and at University College, London, for the past eight years, will also serve as assistant professor of medicine. The Cox Institute was opened, March 18, under the temporary direction of Dr. J. Harold Austin, John H. Musser professor of research medicine in the school of medicine (The Journal, April 16, p. 1388). The staff includes at present Drs. Russell Richardson, who is in charge of the clinic service, Francis D. W. Lukens, Frederick W. Sunderman and Morris A. Bowie.

SOUTH CAROLINA

Society News. — At a meeting of the Eastern Carolina Medical Association, Myrtle Beach, August 11, speakers included Drs. George H. Bunch, Columbia, on "Surgical Treatment of Pulmonary Tuberculosis"; James M. Northington, Charlotte, N. C., "Doctors Should Resume Leadership in Scientific, Civil and Political Affairs" and William R. Barron, Columbia, "Transurethral Prostatectomy."

Roentgen Ray Society Organized.—South Carolina radiologists recently organized the "South Carolina X-Ray Society" at a meeting in Columbia. Dr. Floyd D. Rodgers, Columbia, was chosen president and Dr. Robert B. Taft, Charleston, secretary. Charter members were Drs. Percy D. Hay, Jr., Florence; Oscar D. Baxter, Sumter; Hillyer Rudisill, Jr., Charleston; William S. Judy, Greenville; Thomas A. Pitts, Jr., Columbia; William M. Sheridan, Spartanburg; Frank R. Wrenn, Anderson; Malcolm Mosteller, Columbia; Rodgers and Taft. Meetings will be held in conjunction with the annual meetings of the South Carolina State Medical Association.

WASHINGTON

Personal.—Friends and students of John Weinzirl, Dr.P.H., of the department of bacteriology, University of Washington, Seattle, gave a banquet in his honor recently, celebrating twenty-five years of service to the university.——Dr. Casper W. Sharples, Seattle, was recently reelected president of the Washington Society for Mental Hygiene.——Dr. William O. Copps, Seattle, has recently been appointed medical criminologist for the city police department.

Society News.—A recent meeting of the Klickitat-Skamania Counties Medical Society was addressed by Drs. Alexander H. Peacock, Seattle, on medical economics; John M. Blackford, Seattle, gallbladder disease, and Frederick H. Brush, Yakima, nephritis.——The Walla Walla Valley Medical Society celebrated its fiftieth anniversary and at the same time the fiftieth anniversary in medical practice of Dr. Howard R. Keylor, Walla Walla, at a banquet, June 25.

WEST VIRGINIA

Society News.—Dr. Harry Ryerson Decker, Pittsburgh, addressed a joint meeting of the Monongalia and Preston county medical societies at Hopemont, July 26, on "Surgical Procedure in Suppurative Conditions of the Chest."

New Bridge over the Kanawha.—The Kanawha Medical Society recently unveiled a tablet naming a new bridge over the Kanawha River in honor of Dr. Spicer Patrick, a pioneer of Kanawha County. He lived from 1816 to 1884. General Mason M. Patrick, a grandson of Dr. Patrick and formerly chief of the air service of the United States Army, accepted the tablet for the family.

WISCONSIN

Hospital News.—A hospital annex to the National Soldiers' Home, Milwaukee, recently completed at a cost of $300,000, was opened, August 22. It increased the capacity of the home by 298.——A new building providing sixty beds for St. Camillus Hospital, Milwaukee, was dedicated recently. The former capacity of the hospital was nineteen beds.

University News.—Dr. Rudolf J. Noer, Wabeno, has been appointed assistant in histology at the University of Wisconsin Medical School, Madison, and Dr. Robert C. Bunts, Madison, assistant in pathology. Walter J. Meek, Ph.D., professor of physiology and assistant dean of the medical school, has been appointed a member of the National Research Council for the division of medical science. Dr. Philip Levine, of the staff of Rockefeller Institute, New York, has been appointed instructor in bacteriology.

GENERAL

Narcotics Limitation Convention Not Ratified. — The United States is the only manufacturing country which has thus far ratified the treaty drawn up at the international conference on limitation of the manufacture of narcotic drugs, held in Geneva in 1931 under the League of Nations, according to a recent announcement from Geneva. Nicaragua, Persia, Peru and Portugal, all nonmanufacturing countries, have ratified the convention. Unless twenty-five countries, including four manufacturing countries, have ratified the convention before April 13, 1933, it cannot come into force. Other manufacturing countries are France, Germany, Great Britain, Japan, The Netherlands, Switzerland and Turkey.

Delegates to Goiter Conference.—Plans for assembling an American delegation to the Second International Goiter Conference in Berne, Switzerland, in August, 1933, were adopted by the American Association for the Study of Goiter at its annual meeting in Hamilton, Ont., in June. It was agreed to designate as delegates at large all members of the association who could attend the conference. In addition, delegates from each of twelve geographic sections of the United States have been appointed and others from Canada are to be selected. The United States Army and Navy, the Public Health Service and the various medical and surgical organizations, as well as the leading goiter clinics of the United States and Canada, have also been invited to send delegates. It was decided to invite the conference to the United States for its third session in 1937. Subjects for discussion at the conference will be limited to the hyperthyroses and etiology, with the possible addition of prophylaxis, it has been announced.

Conference on Tuberculosis.—The Mississippi Valley Conference on Tuberculosis and the Mississippi Valley Sanatorium Association will meet in Indianapolis at the Claypool Hotel, September 12-14. According to the tentative program, sessions will be held separately for the two groups. Speakers will include Drs. Ralph B. Bettman, Chicago, "Thoracoplasty—Treatment of Choice When Sanatorium Care Is Unsuccessful"; Jay Arthur Myers, Minneapolis, "Tuberculosis Infection"; Cameron Haight, Ann Arbor, Mich., "Differentiation of Lung Abscess and Pulmonary Tuberculosis"; Allan J. Hruby and Henry C. Sweany, Chicago, "Primary Carcinoma of the Lung"; Arville O. DeWeese, Kent, Ohio, "Tuberculosis in College Health Service"; James A. Edwards, Oakdale, Iowa, "Employment of Tuberculous on Sanatorium Staffs," and George S. Bond, Indianapolis, "Hyperthyroidism and Tuberculosis." Tuberculosis in industry will be the subject of one symposium. Dr. Morris Fishbein, editor of The Journal, will address the annual banquet, Tuesday, September 13, on "The New Frontier in Tuberculosis." Stanley Coulter, Ph.D., dean emeritus, School of Science, Purdue University, Lafayette, Ind., will give the address of welcome.

American Physical Therapy Association.—The forty-second annual meeting of the American Physical Therapy Association will be held in Detroit, September 28-30, under the presidency of Dr. Edwin N. Kime, Indianapolis. Among physicians who will present papers are the following:

Dr. Frank H. Krusen, Philadelphia, "Education in Physical Therapy."
Dr. Curran Pope, Louisville, Ky., "Personal Studies in Pyretotherapy."
Dr. Israel Bram, Philadelphia, "Toxic Goiter: The X-Ray as a Supplement in Nonoperative Therapy."
Dr. Richard Kovacs, New York, "The Cold Quartz Lamp."
Dr. Lewis J. Silvers, New York, "Electrosurgery in Rhinolaryngology."
Dr. Winfield Scott Pugh, New York, "Electrosurgery of the Vesical Neck."
Dr. Walter E. Pennington, Indianapolis, "Diverticulosis of the Gastro-Intestinal Tract."

Government Services

Army Officers' Pay Reduced

Medical officers of the army, navy, public health service, veterans' bureau and all other branches of the government service will suffer a reduction of 8⅓ per cent in their salaries under the provisions of the economy law recently enacted by Congress. In addition, the annual thirty-day leave with pay heretofore allowed will be suspended during the current fiscal year. In lieu thereof such officers will be required to take an annual leave of twenty-four working days on a basis of two working days per month without pay. Medical officers in the army, navy and public health service suffer in addition a reduction in rental allowance from $20 to $18 per room, and their subsistence allowance will be reduced from 60 cents a day to 52 cents a day. Retired medical officers will suffer a reduction of 8⅓ per cent in their retirement compensation. This will affect all retirement pay in excess of $1,000 per annum. There is also a provision in the act which limits pay to $3,000 per annum to all persons receiving pay on account of former service as commissioned officers who are also holding civil service positions, appointive or elective, under the U. S. government. When the salary from either source is more than $3,000, such persons may elect to receive pay of the civil office or retirement pay. Under a decision of Comptroller General J. R. McCarl, interpreting the economy law, it is held that no officer shall be furloughed without pay for more than five days in any one calendar month without the consent of such officer. There is no change in the existing law with reference to officers when absent on account of sickness or disability or lawfully absent from duty and awaiting orders.

Foreign Letters

LONDON

(From Our Regular Correspondent)

Aug. 29, 1932.

The Undiminishing Maternal Mortality

In previous letters the concern caused by the undiminished maternal mortality, while all other mortalities have declined, has been mentioned. A committee of eminent obstetricians appointed by the government to advise on the application to maternal mortality and morbidity of the medical and surgical knowledge at present available has presented its final report. In 48 per cent of the cases a "primary avoidable factor" in the form of omission or inadequacy of antenatal examination, error of judgment in management, lack of facilities, or negligence in following advice, was found. In 1930 there were 4.4 deaths per thousand live births and the figure for puerperal sepsis was 1.92.

PUERPERAL SEPSIS

Sepsis was responsible for 18 per cent of the deaths. The majority were due to sporadic infection and could have been prevented by a conscientious technic. In a fifth of the cases the labor was difficult, and serious injury to the maternal tissue was the most important factor in determining fatal infection. In not less than 85 per cent of the normal cases in which sepsis occurred the agent was Streptococcus pyogenes. In a large proportion, infection was due to transfer of the microbe from the throat or nose of some one in attendance during the first few days of the puerperium. This may occur by droplet spray directly on the vulva or indirectly from hands, instruments or dressings. In some cases the streptococci are conveyed by the mother's fingers from her own throat or nose; also they may have been originally present in her genital tract. In sepsis following difficult labor there is in addition to these modes of infection an increased chance of endogenous infection by anaerobic streptococci or by B. coli, either present in situ or reaching the genital tract from the blood stream. To minimize these dangers the following are recommended: wearing of masks over both nose and mouth by all in attendance on the patient and by others present, use of rubber gloves with scrupulous antiseptic precautions, discouragement of talking in the room of confinement, and avoidance of vaginal examination after rupture of the membranes in a straightforward case.

OTHER CAUSES OF DEATH

In regard to toxemias, the examination of the urine and estimation of the blood pressure during pregnancy are not as effectively carried out as they should be. Midwives should be trained to determine blood pressure. Warning hemorrhage is not sufficiently regarded, and physicians do not make sufficient use of intravenous injection of blood or of transfusion. In the case of toxemia and of warning hemorrhage the woman should be placed in an institution more often and earlier than at present.

IMPERFECTIONS OF THE MATERNITY SERVICE

Imperfections of the maternity service include lack of facilities for training students, inadequate facilities for postgraduate instruction, too little instruction of young obstetricians and gynecologists to establish themselves in nonteaching provincial centers, and imperfect instruction of midwives in antenatal care and nursing methods.

MATERNITY HOSPITALS

Cases of sepsis, whether arising in the hospital or admitted from the outside, should not be treated in a maternity hospital unless an entirely separate block, separate nursing and ward staff, and separate staff accommodation are provided. For emergency or other cases which may be a source of danger on account of potential sepsis, special provision (separate small wards and labor wards with special allocation of staff) should be made. Cases of abortion should not be admitted to ordinary wards. To facilitate specialist treatment of nonobstetric conditions associated with pregnancy and childbirth new maternity accommodation should be associated with general hospitals.

Parental Alcoholism Has No Effect on Offspring

An important report entitled "Alcohol and Inheritance" has been issued by the medical research council. Before the war, Prof. C. R. Stockard of Cornell University published in America the result of experiments to determine the effects produced by alcohol on the fecundity of guinea-pigs and the quality of their offspring. His conclusions, which have been widely quoted, were that the daily administration of alcohol, in quantities sufficient to produce intoxication, caused a fall in the number of births and a liability to weak and defective offspring. Miss F. M. Durham, working at the National Institute for Medical Research, has made a large number of experiments on guinea-pigs, with an adequate number of controls living under identical conditions except for the administration of alcohol. Miss H. M. Woods has collaborated in the statistical analysis. The conclusions are quite contradictory to those of Professor Stockard. The litters from alcoholic parents or their descendants were as numerous and as heavy as in the control experiments. Deformities did not occur more frequently than in the control group, and the offspring for several generations showed no transmitted defects, such as described by Professor Stockard. It is pointed out that his experiments were performed in the days when the science of dietetics was not so advanced, and that supervision of the diet of the guinea-pigs was much more thorough in the present series. For example, a great point was made about the supply of cabbages. It is suggested that in the absence of cabbage from the diet it is possible that alcohol may have affected the breeding power. The guinea-pigs received their alcohol by inhalation while sitting in cages in a special tank. Their general health remained excellent despite daily intoxication following exposures of two or three hours. Thus there was no evidence of injury to the germ plasm.

Birth Control

At the annual congress of the Royal Sanitary Institute, Sir Thomas Horder, who was to have opened the debate on birth control but was unable to be present, contributed a paper in which he described birth control as the most practical method of eugenics available. Fundamentalists believed that it was wrong to interfere with nature, but it was too late in the course of evolution to revive these old ideas. Better and more trustworthy methods of birth control must be discovered. He regarded indiscriminate child bearing as a disease of the body politic and thought that there was need for a course of instruction in this subject. Large numbers of physicians were qualifying every year who had never received any instruction in the matter.

Mr. Harold Chapple, gynecologist, of Guy's Hospital, said that every married couple should have the right and understand the means whereby it would be possible for them to have children at such intervals as they thought fit, having regard to their health, circumstances and other views on the subject. He repudiated the idea that the object of the birth control movement was to make vice easy. It was an intensely serious movement. Thousands of women with heart, lung or kidney touble were dependent on birth control. Were they to be refused any help in a matter of life and death? Half of his patients at Guy's Hospital would disappear under sane birth control.

A clergyman, Canon E. C. W. Rose, said that he was not so sure that birth control would promote public morals. Married love was not dependent on nor limited by physical acts. Human love involved self control. Contraception provided physical satisfaction which was purely temporary at the cost of eliminating those qualities which alone made married love perfect. Approval of the practice of birth control would lead to great abuse among the unmarried.

The Waste of Drugs Under Medical Socialism

In a discussion on the panel system, Mr. W. M. Mashall, secretary of the Scottish Association of Insurance Committees, said that medical authorities proclaimed that "the day of the bottle is passing, and the pathetic belief that every visit or consultation should imply the writing of a prescription is disappearing." Yet under the national insurance scheme more than 50 million prescriptions were issued to insured persons in England and Wales—surely an appalling figure. Physicians had stated that nine tenths of their prescriptions were futile and were merely provided to please the patient. The insured population of Glasgow was 25 per cent more than that of Manchester, yet last year the prescriptions issued by the Manchester physicians cost $400,000 and in Glasgow only half that, although there was just as much illness in Scotland as in England. The demand for medicine in England was a habit rather than a necessity, and the physicians had here a great opportunity for economy.

PARIS

Aug. 3, 1932.

The New Site for the Paris Faculty of Medicine

For a number of years, the lack of space for the growing needs of the laboratories and the constant increase in the number of students at the Faculté de médecine de Paris has made a change of site more and more imperative. The Rockefeller Foundation donated, some time ago, 150,000,000 francs ($6,000,000) for the purpose, on condition that the central government would contribute an equal sum. All that remained to do was to decide on the new site, which would have to be large and yet not too far distant from the residential sections of Paris, to take account of the needs of the professors and their pupils. That is a double requirement difficult to realize. A preliminary meeting was recently held at the ministry of public instruction, under the chairmanship of the minister himself, which was attended by Professor Balthazard, dean of the Faculté de médecine; Professor Roussy, his assistant; Mr. Carléty, rector of the University of Paris; Mr. Cavalier, director of higher education, and representatives of other ministries. The choice fell on a tract of land (formerly used for military purposes) bordering on the southern line of the old fortifications, which is a long distance from the center of Paris. The plan was long discussed but, unfortunately, rejected to locate the new Faculté de médecine on the site of the present Halle aux vins, which, in that case, would have been transported outside of Paris. This site would have been better for the university buildings. Located on the bank of the Seine, alongside the Institut médico-légal, it would not have been too far from the other *facultés* where are installed the publishers of medical works, the shops of the manufacturers of instruments, and the rooming houses for students. The selection of the more distant site will mean a big loss to the interests mentioned. But, as so often happens in France, it was thought necessary to protect the powerful interests of the wine merchants.

Influence of Alcoholism on the Development of Tuberculosis

The predisposing action of alcoholism on the development of tuberculosis has been asserted for some time by French clinicians. It has been one of the most important "weapons" employed in the crusade against alcoholism, and Professor Debove, while he was dean of the Faculté de médecine de Paris, secured permission from the management of the Assistance publique à Paris to put on the walls of all the consultation rooms of the hôpitaux de Paris a placard with these words: "Tuberculosis is contracted in the cabaret." These placards, after the lapse of forty years, have finally disappeared, at the request of the syndicate of the dealers in alcoholic beverages, which urged that the practice was harmful to their interests. Dr. Arnould, director of the Comité national de défense contre la tuberculose, has recently published a statement in the *Presse médicale* to the effect that the foregoing warning was an exaggeration intended to shock the mind into submission. In order not to offend his compatriots, he cited only German statistics in support of his statements. During the decade from 1920 to 1929, the number of cases of cirrhosis of the liver was doubled; the number of cases of drunkenness or alcoholism treated in the hospitals was trebled, while the number of patients treated in the asylums for alcoholic psychosis had increased sixfold. During the same period, tuberculosis mortality, on the contrary, decreased one third. During the years 1922 and 1923, in particular, the figures for alcoholism were at a standstill, and even tended downward, whereas the mortality of tuberculosis increased. The explanation is easy. This was the period of deflation in Germany. The severe economic conditions not only led the population to restrict the consumption of alcoholic beverages but also its regular diet, and it was the latter fact that favored the development of tuberculosis. At present, alcoholism is again increasing, and tuberculosis is again decreasing. Mr. Arnould concludes that the crusade against alcoholism is needed to prevent the degeneration of the race and the development of dangerous psychoses, but that this crusade has no influence on the diminution of tuberculosis, which cannot be brought about other than by the amelioration of general hygienic conditions and the suppression of contagion. There is only one criticism to offer against Dr. Arnould's argumentation, and that is that the statistics that he utilized cover only persons aged 30 to 70. That is, to be sure, the period in which alcoholism makes its chief inroads on the organism; but tuberculosis is most frequent in persons under 30 years of age.

Hygiene in the Artificial Silk Industry

During the past thirty years, the artificial silk industry has developed rapidly in France (where it originated) and in other countries. The various processes employed necessitate the use of many chemical products, some of which have been found to be harmful to the workers and even to persons residing in the vicinity of the factories. Messieurs Cazeneuve, A. Morel and de Leeww recently completed an inquiry into the situation and presented it to the Academy of Medicine. The untoward incidents observed are due to the effects of alcohol, ether, acid and alkaline substances, hydrogen sulphide and carbon disulphide. Mr. de Lapersonne observed cases of conjunctivitis and keratitis resulting from the projection of droplets of sulphuric acid. It is evident, therefore, that extensive measures of protection for the workmen and persons residing in the vicinity of artificial silk plants are urgently required. The authors emphasize the need of apparatus for the mechanical absorption of the gases and the irritating products in the workrooms, together with ample ventilation. These measures have improved conditions to a great extent.

Value of the Radiologic Examination with the Patient in a Vertical Position, Head Downward

It appears that the disarrangement of the organs that results when a patient is placed in a vertical position, head downward, may bring about new and interesting observations during a radiologic examination. At a meeting of the Société de radiologie médicale de France, Dr. Henri Béclère reported recently on his success with this new method of radiographic research. By the "feet toward the ceiling" position, the author does not mean the Trendelenburg position; he means a vertical position with the head downward. The patient is held firmly to the bascule operating table by means of a special stirrup bandage provided with straps that pass across the feet and the knees of the patient. With his hands, the patient holds on to the bars at each side of the table. The region to be radiographed has been previously well studied, for the purpose of the examination in the vertical position is to procure additional information. The fluorescent screen is put in place, and the operating table is raised, with one or two stops, to a vertical position, to see that the screen is in the proper position and to assure the fixation of the patient. When the table is in a vertical position, a roentgenogram is made and the table is then lowered to a horizontal position. The operation requires only a few seconds and the patient is not inconvenienced. There are few regions of the body that, when radiographed under these conditions, do not furnish new and interesting views to aid the diagnosis.

Personal

Dr. Sparks, an American dentist in Paris, has been chosen commander of the department of the American Legion of France. A graduate of the University of Indiana, he took part in the war, at first in the French army medical corps, then as captain in the American army, for which service he was accorded the Cross of the Legion of Honor.

Dr. Camille Delezenne has died at the age of 70. A former associate professor at the Faculté de médecine of Montpellier, he had been appointed professor of physiology at the Institut Pasteur de Paris and had become a member of the Academy of Medicine. His principal researches have been on cytotoxic serums and the hormones of the pancreas. He had just succeeded in isolating insulin when the publication of his article on the subject was nullified by that setting forth the results of the researches of the Canadian investigators.

ITALY

(From Our Regular Correspondent)

July 15, 1932.

The Congress of Medical Radiology

The Società italiana di radiologia held its tenth congress in Parma, under the chairmanship of Prof. Armando Rossi of the University of Parma.

Prof. Raffaele Paolucci, director of the Clinica chirurgica of Parma, delivered the opening address, taking "Pulmonary Abscess" as his subject. Accepting the classification of Baumgartner, which is similar to that of Manfredo Ascoli, the speaker divided pulmonary suppurations into (1) simple abscess of the lung, (2) abscess fetid from the start, (3) chronic suppuration, (4) localized gangrene, and (5) bronchiectasis complicated by abscess. For each of these types he pointed out the most appropriate treatment.

Professor Vallebona of Genoa presented a paper on the radiology of acute pulmonary diseases. Speaking in general of acute pulmonary and bronchopulmonary inflammatory processes, the speaker showed the difficulty of making an etiologic distinction between them, and particularly an anatomopathologic and an anatomoradiologic division. A clinical division is more practical, one of the disorders in question, crupous pulmonitis, having a typical and characteristic clinical course that is generally sufficient for an exact diagnosis of the disease. The speaker described then the radiologic symptomatology of crupous pulmonitis, distinguishing the symptoms of the initial stage of the disease, the symptoms of the crisis, and the aspects of the period of resolution. He dealt with the involvement of the pleura in an acute pneumonic process, and with acute pulmonary processes in anomalies of the lung (lobe of the azygos vein), and considered the radiologic characteristics of pulmonitis in the child. In speaking of bronchopulmonitis, he brought out that the radiologic aspects of this disorder are less typical than those of pulmonitis. Nevertheless, he described several special forms, such as influenzal bronchopulmonitis, postoperative bronchopulmonitis, and the types due to toxic gas and to the

Friedländer bacillus. Of the complications and sequels of acute pulmonary processes, the attention of the radiologist is attracted chiefly by abscess and by pulmonary gangrene, disorders that may also be primary. Often it is impossible to make a frank differentiation between the two diseases; the differential diagnosis must take account also of the possibility (although rare) of an interlobal pleuritis. According to the speaker, the importance, in acute diseases of the lungs, of a radiologic examination of the patient has been heretofore too little recognized.

Nicotra of Catania discussed the radiology of chronic pulmonary diseases, distinguishing morbid forms due to (1) an inert pathogenic agent and (2) a biologic pathogenic agent. The former are characterized also in the roentgenogram by tissue changes of the fibrous type; in the absence of exudative phlogosis demonstrable radiologically. Pneumonoconiosis, which is the most characteristic of the disorders due to an inert pathogenic agent, has as an elementary change the pneumonoconiotic nodule, the accumulation of which leads to complex conditions. The inhaled particles of dust are deposited chiefly in the more cortical, subpleural areas of the lung—in the axillary and paraxillary regions. In miliary tuberculosis, however, the foci are distributed uniformly, with greater density in the parahilar regions.

The diseases due to an etiologic biologic agent are characterized by inflammatory exudative processes. Of these the speaker distinguished four groups: those due to (1) animal parasites, (2) vegetable parasites, (3) syphilis and (4) tuberculosis. For each group he gave the principal radiologic characteristics and pointed out that syphilis causes a notable fibrous hyperproduction, and the forms of a tuberculous nature occur as a peculiar feature of bronchiogenic metastatic dissemination. In tuberculosis, the radiologic aspects of a single focus represent initial manifestations (primary infection and reinfection, Kuss-Ghon focus, Assmann infiltrate, lobitis). In the group of manifestations with multiple foci, the speaker distinguished those with foci all alike and those with foci of various aspects. Of the manifestations with like foci, he described miliary tuberculosis and tuberculosis acinonodosa. Among those with manifold and different radiologic aspects, he distinguished cavitary formations and metastasis with acinonodose foci and cavitary formations and metastasis with lobular foci (bronchopulmonitis). In a general way, it may be stated that aspecific diseases do not give rise to cavitary or metastatic radiologic images, whereas these are characteristic of tuberculosis. Following the general discussion of the papers, the society passed a resolution demanding of the Federazione nazionale per la lotta antitubercolare that a compulsory radiographic record card be introduced, so that specific initial lesions found in school children may be recorded therein from early childhood.

Vespignani of Padua presented the official paper on radiology of the disorders of the small intestine. He considered, for the purposes of his study, the subvaterian portion of the duodenum as the beginning of the small intestine and the ileocecal valve as the distal extremity. The speaker emphasized the conception of duodenal mobility, which he regards as not sufficiently recognized, and raised the question as to whether the movements of the duodenum are to be regarded as physiologic. Duodenal stasis, diverticula and tumors of the duodenum owe to radiology the possibility of an exact identification. Vespignani described also a rare case of encapsulated visceral fibrous peritonitis, controlled at the operative table by Fasiani. Only twenty-two cases of this disorder have been described in the literature. He dealt with the small intestine in connection with operations for gastro-enterostomy and the complications that frequently follow that operative intervention; less common are duodenojejunostomy and ileotransversostomy.

Piccinino of Naples considered radiologic research in diseases of the large intestine. He distinguished the defects of position, with a constant radiologic picture and definite clinical symptoms, including changes in position, associated with deficiencies of the ligaments. Among the defects of conformation he described the megacolon and the dolichocolon. Considerable importance attaches to radiology for the light it has thrown on intestinal motility, the mechanism of which has been clarified while the study of the physiopathology has been advanced. Among the disturbances of the canalization of the large intestine are to be considered intestinal occlusion, stenosis and invagination. The principal inflammatory processes are appendicitis, colitis and intestinal tuberculosis. Diagnostic investigation of diverticula of the colon, of fistulas and of tumors finds in radiology a potent aid.

Bellucci of Perugia spoke on lesions due to rays, considered from the biologic point of view, dealing more particularly with lesions caused by roentgen rays and by radium. Since the action of rays is always destructive whatever the dose, the term "lesion due to rays" assumes a much wider significance than is attributed to it in a medicolegal sense or from the point of view of workmen's compensation, and the subject has a wide range and depth. The speaker dealt with the biologic factors of lesions due to rays and the biophysical factors that intervene not only in diagnosis but also in therapy—and in professional roentgenologists. Speaking of the general characters of lesions due to rays, he divided them into three large groups: local, general and *à distance*. The local and the general lesions may be immediate or remote; great importance attaches also to postirradiation changes in the blood plasma and in organic exchange. The speaker recalled the influence that irradiations may have on the genesis of blood disease and of endocrine syndromes, on receptivity and the course of acute diseases and of tumors, on the fetus and on posterity. In conclusion, he dealt with the biologic mechanism of the production and the reparation of lesions due to rays.

Ratti of Milan took up the functional and organic changes due to irradiations. Considering occupational lesions, the speaker stated that the persons most exposed are the radiologists, the physicists and the sanitary personnel. The site of predilection is the skin, particularly the hands; next comes the hematopoietic system (aplastic anemia; possibly also leukemia), and finally the genital region and the body skeleton. The only person who, at the present time, cannot be completely protected is the medical radiologist himself.

The Società di radiologia elected Professor Siciliano of Florence as its new president. The city of Perugia was chosen as the meeting place of the next congress.

Meeting of Sanitarians of Civil Hospitals of Genoa

The sanitarians of the civil hospitals of Genoa met recently under the chairmanship of Professor Da Gradi. Gervino and Vaccari spoke on the modern treatment of gastroduodenal ulcers. The method that they employ is jejunal feeding with the sound, combined with treatment with atropine and pepsin. The speakers brought out the difficulties of such treatment owing to the necessity of frequent radiologic control, which restricts the use of the method in ulcerations of the lesser curvature. The results that they have secured are, however, superior to those obtained by any other form of treatment, and amount to 60 per cent of recoveries as controlled thus far.

Durante expatiated on the resection of the scalene muscles in pulmonary tuberculosis. In addition to the operative technic, the speaker described a special instrument that he employs to facilitate the rapid section of the scalene muscles, either separately or combined with the section of the phrenic nerve and the posterior thoracic nerve. He mentioned also the most recent research, accounts of which have appeared in the world literature, tending to direct surgery of the pulmonary lesions toward the suppression of inspiratory excursions controlled by the scalene muscles.

Vignolo described a rare case of bilateral osteochondritis of the hip joint in a child, aged 6, who presented also a movable body, in the right knee joint, of the size of a lentil. Movable bodies of the joints are rare in children, and it is advisable to postpone surgical intervention, waiting to see whether the movable body increases in size and causes increased functional disturbances.

Trevisanello spoke on epidemic hiccup, describing four cases that he observed simultaneously in persons who were not living in close contact and who did not present at the time any influenzal or encephalitic symptomatology. The speaker cast doubt on the existence of a true epidemic hiccup, in the sense of an independent disease entity, as described by some modern authors, and regards such a morbid manifestation as merely a symptom.

MADRID

(From Our Regular Correspondent)

July 17, 1932.

Water Supply of Madrid

The director of water of Madrid recently lectured before the Sociedad de Higiene on the water supplied by the canals of the Lozaya Springs, which furnish Madrid with a daily average of 218 liters of water per inhabitant. Ten cities in the United States and three European cities receive a larger daily output from their water supplies (500 liters per inhabitant daily each of the ten cities in the United States and 268 liters each of the European cities). Twenty-four other large cities receive a still smaller daily output than that given by the Lozaya supply to Madrid. In this group may be placed London, Vienna and Berlin, with a daily output of 168, 161 and 118 liters, respectively, per inhabitant. In 1928 the government authorized an expenditure of 120,000,000 pesetas ($10,800,000). When the supply plant was established, eighty years ago, with Dr. Bravo Murillo as a director, 129,000,000 pesetas ($11,610,000) was spent. At that time Madrid had 200,000 inhabitants, while now it has more than a million Improvements have been made in the water supply plants, including the enlargement of one of the canals to more than one third of its former capacity, the installation of 100 kilometers of new pipes in the suburbs of Madrid, and the construction of a new canal costing $4,500,000, which will be ready next year. The water supplying Madrid is of excellent quality. The basin of the springs is naturally formed by hard granite. The water cannot become turbid or contaminated because the basin is protected by the dams of Villar and Puentes Viejos, constructed in 1879 and in 1920, respectively. The water reaches the city pleasantly cool, more so since 1911, when a transverse canal was constructed. Both the plants and the aqueduct are well protected against contamination The town of Buitrago, where the springs are located, is small. Nevertheless the committee in charge of the water supply of Madrid maintains a public health brigade, guards for the care of the plants and of the canals and a hospital with a capacity of eight beds. The members of the small medical center may communicate with the members of the central branch and of the laboratories of the Lozaya canals, among whom there are prominent specialists and bacteriologists, whenever necessary. The Lozaya canals furnish an abundant supply of water to several towns near Madrid. The sanitary regulations are enforced by competent officials and the water passes through a process of double chlorinization by the Wallace and Tiernan system.

Trypanosomiasis in Spanish Territories

The Madrid branch of the Association of Physicians of the Spanish Colonies recently presented before the government a report on health conditions of the Spanish territories in the coast of the Gulf of Guinea, with especial reference to the frequency of trypanosomiasis. In the city of Bata the mortality caused by trypanosomiasis, which some years ago was small, reached 12 per cent in 1930, and 42 per cent of the deaths from all diseases in 1931. The unsatisfactory conditions of health on the coast of the Gulf of Guinea cannot be considered due to economic conditions. The government of Spain is generous in matters of sanitary services for the colonies. Seventy pesetas ($6.30) for square kilometer and 11 pesetas ($0.99) for each inhabitant are allowed in Spanish colonies for public health purposes, while there is an allowance of 9.4 francs ($0.84) per square kilometer and 3.1 francs ($0.28) for each inhabitant in the French colonies Gabon and Camerun. In the report of the colonial physicians it is stated that the inhabitants of some nearby colonies have suspended migration toward Spanish Guinea because the health conditions of that region are not satisfactory.

Congress of Ophthalmology

The Sociedad Oftalmológica hispanoamericana is now holding its seventeenth congress in the Casa de Salud de Valdecilla, in Santander. Ocular microscopy is the official topic of the congress. Microscopy of the vitreous body will be the official topic for the next congress. The discovery of the so-called double slit lamp for the examination of the eye, made by Dr. Lacarrere, has enabled ophthalmologists to make important studies on pathologic conditions of the cornea. Prof. Novoa Santos believes that Dr. Lacarrere's discovery will solve certain problems offered to the ophthalmologists by intern physicians, making it possible to recognize certain disturbances of general nutrition by the presence of lipoid degeneration of the cornea. Dr. Lacarrere is the general secretary of the seventeenth congress, now in session.

Women Physicians in Spain

Dr. Carablas recently lectured on the subject of women in the medical profession. He stated that the first Spanish woman physician, Martina Castañeda, graduated in Madrid in 1882. When she graduated, all the schools closed for the day, and the students paraded, with music and banners. At present there are about 100 women physicians in Spain, some of whom are in prominent positions. Women physicians have better opportunities to practice in Spain than in some other countries. In France there are several thousand women physicians, some of whom are famous, but no woman has been given any position in the board of public health of the state, nor in a hospital as intern physician. The last congress of the International Association of Women Physicians was surprised when informed that both Drs. Soriano and Garcia de Cosa had positions in the civil navy of Spain.

Distress Among Spanish Physicians

Recent statistics seem to show that about 10,000 physicians have no practice. The schools of medicine annually graduate about 1,000 new physicians, while the annual mortality of physicians is about 200. The profession has remained indifferent to its own interests by permitting members of subordinate professions, such as midwives, nurses, dentists, chiropodists and masseurs, to enter fields which should be reserved for physicians. These factors have brought on a condition of misery and hunger in many homes of physicians. In order to remedy this situation, if possible, a general meeting has been called, to be held at Madrid on a date to be announced later. Physicians who wish to help to remedy this critical condition in the profession are requested to send their plans to the committee on organization, in charge of Dr. Pio Brezosa Tablares, Calle Salmeron, No. 100, Barcelona, Spain.

Mental Hygiene

The Liga Española de la Higiene Mental recently held several meetings in Madrid. Mr. Azaña, president of the Council of Ministers of Madrid, said at the inaugural meeting that the government is deeply interested in mental hygiene. When the meetings were over the following petitions were sent to the government: In order to preserve mental hygiene it is advisable to stop all noises in the cities, especially near hospitals, all the time, and near colleges and schools during classes and in the entire city during certain hours of the night. It seems advisable to prohibit the daily papers from publishing pictures depicting crimes, as well as descriptions of suicides, robberies and similar acts. The relation between alcoholism and mental diseases is evident. Alcoholism should be attacked not by means of prohibition but through scientific measures enforced by the government. Whereas modern psychiatry cares for psychiatric patients in dispensaries, hospitals and colonies, there are no colonies for psychiatric patients in Spain. The Liga asked the government to establish an asylum near Madrid, with departments for psychopaths, drug addicts and dangerous persons of all ages.

Meeting of Socialists

Several Spanish physicians of the socialistic party met recently in La Casa del Pueblo de Madrid to organize a national federation of Spanish syndicalized physicians. Dr. Verdes Montenegro was president of the meeting. The members of the congress passed resolutions of confidence in the general director of public health, who is a socialist of great political activity. The members of the congress also passed resolutions of solidarity with their Russian comrades in the defense of the proletarian revolution.

Lectures on Tuberculosis

Dr. L. Bernard, professor of phthisiology of the Faculty of Medicine of the University of Paris, recently lectured before the Escuela de Sanidad of Madrid on the progress recently made on phthisiology as applied to the antituberculous crusade. Tuberculosis is a contagious disease. Contagion, as a rule, takes place between human beings, especially through the sputum. The patients should be isolated from the rest of the healthy community. Good methods for isolation of tuberculous children are the Grancher and Bernard methods. In the crusade against tuberculosis the therapeutic knowledge recently acquired, such as the performance of ambulatory pneumothorax and the administration of B C G to the new-born, are of great importance. Ambulatory pneumothorax should be performed only in the dispensaries. The harmlessness of B C G and its preventive value seem to be proved. After the tuberculous patient has obtained complete recovery, an important problem is that related to the proper kind of work he can undertake. Frequently the patients are advised to do farm work. However, this kind of work sometimes demands too vigorous physical exercise.

Prof. A. Saenz of Uruguay, a member of the Institut Pasteur of Paris, recently gave a lecture before the Escuela Nacional de Sanidad of Madrid on the value of B C G in the prevention of tuberculosis. He is enthusiastic about the vaccine. A careful study of statistical data given to the Institut Pasteur of Paris on the results of the vaccination in forty-six countries (not including France, which has special statistics), pointed out that a total of 443,656 infants of less than 1 year of age received the vaccination. Among the general rate of infant mortality from all diseases, 7.9 per cent was among infants who had received B C G and 15.3 per cent among infants who had not received it. The results point out that B C G caused a diminution of 50 per cent in the infant mortality from tuberculosis.

Radio Lectures Given by Hospitals

The hospitals of Barcelona are going through a crisis. Last February the directors of several hospitals asked the assistance of the public and stated that if help could not be secured the number of beds would have to be reduced. The present national crisis has decreased the amount of donations to hospitals. Some money previously devoted to the general welfare services is now applied to salaries of some municipal departments. Several attempts were made to help the hospitals but failed; for instance, a football game was played, but the organizers encountered a deficit, which they wanted the hospital to cover. Now some radio lectures have been organized by the hospitals and they promise to be successful. The two most popular speakers of Cataluña have employed all their wit and ability to raise money for the hospitals. Every time a donation of more than 100 pesetas ($9) is received, the name of the donor is broadcast with great enthusiasm. This brought about a doubling of the efforts of persons to raise more than 100 pesetas. The result is that in a few months 85,000 pesos ($38,250) has been collected, which, if added to amounts obtained from other projects would bring a grand total of 500,000 pesetas ($45,000) given by the public of Barcelona to their hospitals. However, the amount is comparatively small. The amount given to the Hospital de la Santa Cruz has not even paid the coal bill. The directors of the five most important hospitals of the city of Barcelona have again addressed the public for help and insist that the present situation of the hospitals cannot continue.

VIENNA

(From Our Regular Correspondent)

July 20, 1932.

Congress of International Society for Speech Defects

The fifth Congress of the International Society for Logopedics and Phoniatrics was held recently in the Physiologic Institute at Vienna, under the chairmanship of Professor Fröschel. The attendance was unusually large, and eleven countries of Europe were represented. Professor Fröschel discussed the fundamental causes of speech disturbances and their connection with disturbances of other psychic functions. Professor Pötzl discussed aphasia in persons who speak several languages, and gave the results of his studies on the changes in the architectonic structure of the cerebrum in deafmutes. Professor Marburg spoke on the rôle of the cerebellum and the midbrain with respect to speech. Considerable interest centered in the address of Dr. Feuchtwanger of Munich and that of Frau Dr. Jelinek on the brain changes in patients with disturbances of the musical sense. The condition described as depersonalization of speech (a feeling of strangeness toward one's own speech) was studied by Dr. Hoff and by Dr. Silbermann in persons with brain injuries, while Feuchtwanger and Goldzieher discussed disturbances of writing occurring under the same conditions. Professor Merész of Budapest presented a paper on stammering, in which he brought the mental factors into relation with organic manifestations. During the general discussion that followed, the subject was further elaborated from the standpoint of hereditary research (Dr. Szondi); from the standpoint of the graphologic observations, and from the clinical standpoint (E. Mohr). A lively discussion was precipitated by the paper of Dr. Weiss on the stroboscopic examination of the vibrations of the vocal cords. Several new types of apparatus for this purpose were demonstrated by Dr. Stern of the Vienna Institut für Sprachkrankheiten; also by Drs. Stein and Rudin, who have constructed a portable stroboscope. Prof. J. Tarneaud of Paris discussed the theory and treatment of functional disturbances affecting the voice, while Dr. Van Thal of London spoke on "Lisping." Peculiar interest attached to the address of Dr. Zemen on "The Interpretation of Speech Curves," and also to that of Professor Flotau on spastic disturbances of the voice by overexertion, especially in singers. An instructive demonstration was presented by Dr. Némai of Budapest, who discussed the development of the larynx through an ascending series of mammals, from the standpoint of comparative anatomy. Director Soucek of Prague spoke on the development of speech in the school for deafmutes, while Frau Dr. Jelinek described the methods and the technic of auditory exercises in hardness of hearing. Considerable time was devoted to papers on the aid given in various countries to persons with speech defects. Madame Dr. van Dantzig of the Netherlands, Dr. Russell of Ohio and Dr. Segrè of Turin spoke on the arrangements in their respective countries. In conclusion, Professor Fröschels discussed the treatment of disorders affecting the voice in singers. Dr. Hajek gave a series of demonstrations based on the collections in the phonographic archives of the Vienna Academy of Sciences. It was the general opinion that the transactions had been a complete success.

The Death of Rudolf Kraus

The news of the sudden death of the bacteriologist Rudolf Kraus, in Santiago, Chile, at the age of 63, awakened great sorrow in Vienna. Kraus was a genuine Viennese, and unfortunately had suffered the fate that befalls so many Viennese. He studied internal medicine under Neusser and became assistant to Professor Paltauf, the creator of experimental pathology. He acquired scientific importance through his research in the field of serology. He established the serotherapeutic institute in Vienna, where he devoted himself especially to the study of precipitins—his most significant discovery. These researches constituted one of the bases for the development of the theory of immunity. He was intimately engaged in combating epidemics, and hence was called to aid in the suppression of cholera during the Serbo-Bulgarian war. In 1912 he was invited to Buenos Aires to superintend the erection and organization in that city of the state bacteriologic institute. Ten years later, he was called to establish the institute in Brazil for the securing of snake venom. Two years later he returned to Vienna, where he hoped to be appointed head of the department of experimental pathology at the University of Vienna, since, with the death of Paltauf, he appeared to be the only scientist who had had the necessary training for the post. He was destined to suffer a keen disappointment. All sorts of intrigues prevented what would have been a most fortunate choice. The chair was left vacant, ostensibly by reason of economy, but in reality he was opposed by a certain group because he was not of "purely German" blood. Indignant at such treatment, he turned his back on Vienna and accepted a call from the government of Chile to reorganize the public health service of that country. With the death of Rudolf Kraus, Vienna's "medical school" loses one of its most eminent representatives of recent decades.

Increase in Mortality from Almost All Diseases

The statistics of the public health service furnish an instructive picture of the morbidity and mortality as they have developed in recent years under the influence of the prevailing economic conditions. It is indisputable that the figures bearing on these factors show a constant increase. If one compares the mortality figures of 1925 with those of 1930, one notes in diseases of the nervous system an increase of 340 deaths; in pneumonia, 4,000; in diabetes, more than 2,000; in heart disease, more than 6,000; in neoplasms, even 8,000. It is held that the cause for the much higher mortality from pneumonia as compared with the prewar period lies in the reduced resistance of a large portion of the population because of defective nutrition. In explanation of the disorders of the circulatory organs, in addition to defective nutrition attention is called to the psychic factor represented by the manifold worries, and to the present tendency to carry devotion to sport to the stage of exhaustion. Possibly improved diagnosis would explain the "alleged" increase of diabetes. As a parallel observation, one may take the supposed increase of cancer, which may be found to be due chiefly to the perfected means of diagnosis. At present, more patients are going to physicians, and they are seeking a physician in earlier stages of disease. In tuberculosis alone, the number of deaths has been reduced by 10 per cent, during the quinquennium, as a result of the prophylaxis effected by the social aid stations for the tuberculous and the extensive early therapeutic aid afforded by sanatoriums and hospitals.

Marriages

M. A. Flatley, Antigo, Wis., to Miss Honora M. Flawley of Eau Claire, in New York, July 13.

Sam Perkins Bailey, Brooklyn, to Miss Annie Mary Gracey of Franklin, Tenn., in June.

James T. Quattlebaum, Columbia, S. C., to Miss Anne Elizabeth McMaster, June 25.

Clarence T. Risley to Miss Marion Olmstead, both of Conneaut, Ohio, July 9.

Alfred E. Dodson, Medford, Ore., to Miss Ruth V. Swanson, June 19.

Erle Leslie Biggs, Starke, Fla., to Miss Ethel Melba Griffin, June 15.

Henry J. Rettig to Miss Margaret Stepka, both of Milwaukee, July 2.

Deaths

Nathaniel Allison ⊕ chairman of the division of orthopedic surgery of the University of Chicago School of Medicine, died at La Jolla, Calif., August 30, of heart disease. Dr. Allison was born in St. Louis in 1876. He received his M.D. degree from Harvard University in 1901. Following a term of service in the Boston Children's Hospital from 1902 to 1903, he became dean and professor of orthopedic surgery in the Washington University Medical School, St. Louis, and held this position from 1909 to 1923. During the World War he served as chief of orthopedic surgery in the American Expeditionary Forces in France and received the Distinguished Service Cross in recognition of his service. In 1923 he returned to Harvard University Medical School as professor of orthopedic surgery, which position he held until 1929, when he became head of the orthopedic department in the University of Chicago. When in Boston, Dr. Allison was also chief of orthopedic surgery in the Massachusetts General Hospital and director of the Boston School for Crippled Children and the Boston School for Occupational Therapy. In Chicago he was associated with the Gertrude Dunn Hicks and Adele McElwee Memorial hospitals and with the Home for Destitute and Crippled Children. He was president of the American Orthopedic Association in 1922 and also a member of other medical and surgical organizations. He contributed many articles on his specialty to medical literature. He was also co-author with Ghormley of "Diagnosis in Joint Disease." In the American Medical Association he served as chairman of the Section on Orthopedic Surgery from 1914 to 1915. He rendered especially valuable service as a member of the Cooperative Committee on Fractures, which arranged exhibits on this subject at most of the recent annual sessions of the American Medical Association. He cooperated also in the publication of "The Outline of the Treatment of Fractures," issued by the Association.

John Lyman Peck, Scranton, Pa.; Hahnemann Medical College and Hospital of Philadelphia, 1897; member of the Medical Society of the State of Pennsylvania; fellow of the American College of Surgeons; surgeon in chief to the Hahnemann Hospital; surgeon to the Mercy Hospital, Scranton; consulting surgeon to the Wyoming Valley Homeopathic, Wilkes-Barre and the Wayne County Memorial Hospital, Honesdale; aged 62; died, July 28, of heart disease.

Leigh A. Fuller ⊕ Colonel, U. S. Army, retired, Oswego, N. Y.; University of Virginia Department of Medicine, Charlottesville, 1893; entered the Army as an assistant surgeon in 1896; veteran of the Spanish-American War; was promoted through the various grades to that of colonel in 1917; was retired in 1922 after twenty-six years' service; aged 63; died, July 28, in Fort Ontario, of acute dilatation of the heart, arteriosclerosis and myocarditis.

Noble Robert Townsend, Arkadelphia, Ark.; Hospital College of Medicine, Louisville, Ky., 1889; Medical Department of the Tulane University of Louisiana, New Orleans, 1897; member of the Arkansas Medical Society; also a minister; physician and surgeon to the Ouachita College; part owner of a hospital bearing his name; aged 66; died, June 24, of coronary thrombosis.

Alexander Stewart Monro, Vancouver, B. C., Canada; University of Manitoba Faculty of Medicine, Winnipeg, 1896; fellow of the American College of Surgeons; past president of the Canadian Medical Association; consulting surgeon to the Vancouver General Hospital; aged 60; died, August 12, in the Saskatoon (Sask.) City Hospital, of heart disease.

Harold Adams Gale, Winchester, Mass.; Harvard University Medical School, Boston, 1901; member of the Massachusetts Medical Society and the New England Pediatric Society; on the staff of the Winchester Hospital; aged 55; died, July 21, at Laconia, N. H., of septic peritonitis following ruptured diverticulum of the sigmoid.

Ira Joslin Prouty ⊕ Keene, N. H.; Medical Department of the University of the City of New York, 1882; fellow of the American College of Surgeons; formerly member of the board of health and school board of Keene; surgeon to the Elliot Community Hospital; aged 74; died, July 31, of chronic myocarditis and interstitial nephritis.

Mark W. Peyser, Richmond, Va.; University of Virginia Department of Medicine, Charlottesville, 1890; member of the Medical Society of Virginia; for many years secretary of the Richmond Academy of Medicine; on the staff of the Stuart Circle Hospital; aged 62; died, July 29, of carcinoma of the bronchus and chronic arthritis.

Robert Henry Goodier, Hannibal, Mo.; Missouri Medical College, St. Louis, 1883; past president of the Missouri State Medical Association and the Marion County Medical Society; past president of the Missouri State Board of Health; aged 71; died, July 22, in the Levering Hospital, of myocarditis and chronic interstitial nephritis.

Plynn Morton Bolton, Stillwater, N. Y.; New York Homeopathic Medical College and Flower Hospital, 1914; member of the Medical Society of the State of New York; served during the World War; aged 41; died suddenly, July 23, in the Leonard Hospital, Troy, of acute hemorrhagic nephritis.

John Philip Carroll ⊕ Woburn, Mass.; Dartmouth Medical School, Hanover, N. H., 1898; formerly member and chairman of the board of health; aged 57; on the staff of the Charles Choate Memorial Hospital, where he died, July 31, of complications, following an operation for appendicitis.

Harold Francis Miller, Worcester, Mass.; Ohio State University College of Medicine, Columbus, 1926; member of the Massachusetts Medical Society; on the staff of the Worcester Memorial Hospital; aged 30; died, July 16, in Shrewsbury, of pulmonary tuberculosis.

Walter Stewart, Memphis, Tenn.; Memphis Hospital Medical College, 1889; formerly superintendent of the Western State Hospital, Bolivar, and the Memphis General Hospital; aged 65; died, June 26, in the Baptist Memorial Hospital, of carcinoma of the colon.

John Merl Frick, Toledo, Ohio; Rush Medical College, Chicago, 1902; member of the Ohio State Medical Association and the American Proctologic Society; on the staff of St. Vincent's Hospital; aged 53; died, July 13, of a self inflicted bullet wound.

Lorraine Lambert Schwartz ⊕ Pittsburgh; Jefferson Medical College of Philadelphia, 1903; fellow of the American College of Physicians; aged 58; on the staff of the Mercy Hospital, where he died, July 25, of skull fracture sustained in a fall.

John K. Henry ⊕ Mauch Chunk, Pa.; Medico-Chirurgical College of Philadelphia, 1890; for twenty-five years director of the schools of Mauch Chunk; member of the local board of health for thirty years; aged 71; died, July 13, of pneumonia.

Eugene Holden Goldberg, Kearny, N. J.; College of Physicians and Surgeons in the City of New York, 1889; member of the Medical Society of New Jersey; formerly mayor; aged 63; died, June 13, of cerebral hemorrhage.

Milo Mason Loomis ⊕ Manilla, Iowa; Rush Medical College, Chicago, 1897; president of the Crawford County Medical Society; formerly president of the school board; aged 58; died, July 16, of injuries received in an automobile accident.

Samuel Ingram Muller, Long Island City, N. Y.; Long Island College Hospital, Brooklyn, 1914; member of the Medical Society of the State of New York; aged 40; died, July 11, of coronary thrombosis and arteriosclerosis.

John Warren Bail, Brookline, Mass.; Harvard University Medical School, Boston, 1903; member of the Massachusetts Medical Society; aged 55; died, July 16, at his summer home in Duxbury, Mass., of coronary occlusion.

Daniel M. Adams ⊕ Panama City, Fla.; Georgia College of Eclectic Medicine and Surgery, Atlanta, 1912; part owner of the Panama City Hospital; aged 52; died, July 17, in a hospital at Dothan, Ala., of a bullet wound.

Eroll Samuel Hopper, Alamo, Tenn.; Memphis Hospital Medical College, 1911; member of the Tennessee State Medical Association; aged 46; died, July 2, in the Baptist Memorial Hospital, Memphis, of tumor of the brain.

Theodore B. Ford, Columbia, Miss.; Medical Department of the University of Louisiana, New Orleans, 1870; formerly member of the state legislature and state senator; aged 83; died, July 21, of chronic myocarditis.

Willis Joseph Kirkbride ⊕ Toledo, Ohio; University of Michigan Medical School, Ann Arbor, 1901; aged 53; on the staff of the Robinwood Hospital, where he died, July 20, following an operation for appendicitis.

Waldemar J. Sieminowicz, Chicago; College of Physicians and Surgeons, Baltimore, 1893; College of Physicians and Surgeons, Chicago, 1895; aged 72; died, June 13, of carcinoma of the rectum and chronic nephritis.

Philipp Henry Letourneau, Waukon, Iowa; Chicago Medical College, 1881; formerly mayor, health officer and member of the school board; aged 71; died, July 13, of carcinoma of the bladder and prostate.

William Smith Tharp, Sioux City, Iowa; Jefferson Medical College of Philadelphia, 1879; formerly professor of genito-urinary diseases at the Sioux City College of Medicine; aged 75; died, July 3, of heart disease.

Stephen Grant Olmstead, East Stanwood, Wash.; University of Michigan Medical School, Ann Arbor, 1894; member of the Washington State Medical Association; aged 65; died in July of chronic myocarditis.

Henry Harrison Atkinson ⊕ Fordyce, Ark.; Memphis (Tenn.) Hospital Medical College, 1904; president of the Dallas County Medical Society; aged 52; died, June 6, of disease of the kidneys and heart disease.

Michelle Arnold Morin, New Egypt, N. J.; University of Pennsylvania School of Medicine, Philadelphia, 1898; aged 76; died suddenly, April 2, in the St. Francis Hospital, Trenton, of coronary thrombosis.

John S. Horner ⊕ West Pawlet, Vt.; University of Vermont College of Medicine, Burlington, 1892; health officer of Pawlet; aged 64; died, June 19, of septicemia complicated with chronic nephritis.

Francis M. Gustin, Union City, Ind.; Hahnemann Medical College and Hospital, Chicago, 1881; formerly secretary of the city board of health; aged 77; died, June 24, in the Union City Hospital.

Frederick P. Griswold ⊕ Meriden, Conn.; College of Physicians and Surgeons in the City of New York, 1876; on the staff of the Meriden Hospital; aged 82; died, June 27, of heart disease.

Mark Calvin Rabert, Phoenixville, Pa.; Medico-Chirurgical College of Philadelphia, 1915; on the staff of the Phoenixville Hospital; aged 41; died, May 15, in the Allentown (Pa.) Hospital.

William McNaul, San Miguel, Calif.; Cleveland College of Physicians and Surgeons, Medical Department of the University of Wooster, 1884; aged 75; died, June 18, of diabetes.

James Branch Taylor, Oakland, Calif.; College of Physicians and Surgeons in the City of New York, 1882; aged 81; died, in July, of chronic myocarditis and bronchopneumonia.

J. Keller Johnson, Mount Sterling, Ky.; University of Louisville (Ky.) School of Medicine, 1888; aged 68; died, July 23, in a hospital at Lexington, of cerebral hemorrhage.

Samuel Iglick ⊕ Orland, Calif.; Columbus (Ohio) Medical College, 1888; aged 77; died, July 7, of pneumonia, as the result of an injury received in an automobile accident.

Leonard Hugh Ford ⊕ Russellville, Ala.; Chicago College of Medicine and Surgery, 1915; aged 47; died, July 13, in a hospital at Florence, of a fracture of the skull.

Samuel Neely Hutchison, Long Beach, Calif.; University of Arkansas School of Medicine, Little Rock, 1915; aged 39; died, May 28, of coronary arteriosclerosis.

Leroy Henry, San Fernando, Calif.; Medical College of Indiana, Indianapolis, 1893; aged 71; died, May 30, of ethmoid sinusitis with endocarditis and meningitis.

Enos E. B. Beatty ⊕ Newton, N. J.; Medical Department of the University of the City of New York, 1887; aged 70; died suddenly, July 9, of heart disease.

Frederick William Lange, Scranton, Pa.; Hahnemann Medical College and Hospital of Philadelphia, 1890; aged 70; died, July 9.

Charles P. Curtis, *Decatur, Ga.; Georgia College of Eclectic Medicine and Surgery, Atlanta, 1908; aged 73; died, May 2, in Brea, Calif., of chronic myocarditis.*

Frederick F. Gano, *Newark, Ill.; Medico-Chirurgical College of Philadelphia, 1899; aged 58; died, June 18, in Aurora, of diabetes mellitus and pyelonephritis.*

Edwin Murray Mann, *Kenbridge, Va.; University of Virginia Department of Medicine, Charlottesville, 1889; aged 64; died, July 2, of cerebral hemorrhage.*

Albert Alexander Milliken, *San Francisco; Cooper Medical College, San Francisco, 1889; aged 65; died, June 10, in Woodland, Calif., of heart disease.*

Benjamin Franklin Clarke, *San Jose, Calif.; Medical College of the Pacific, San Francisco, 1877; aged 78; died, June 23, of heart block and arteriosclerosis.*

Charles C. Huston ✠ *Knox, Pa.; Detroit College of Medicine, 1911; aged 46; died, August 8, in the Oil City (Pa.) Hospital, of paratyphoid fever.*

Leonard A. Slater, *Richmond, Va.; University of Maryland School of Medicine, Baltimore, 1891; aged 63; died, May 19, of cerebral hemorrhage.*

Gabriel Hardin Funk, *Oklahoma City; University of Louisville (Ky.) School of Medicine, 1890; aged 64; died, May 28, of angina pectoris.*

Isidor Stein, *New York; University of Prague, 1888; aged 68; died, June 25, in the Mount Sinai Hospital, of sepsis and multiple lung abscesses.*

Charles J. Welsh, *Clyde, Kan.; Bennett College of Eclectic Medicine and Surgery, Chicago, 1894, aged 73; died, June 23, of cerebral hemorrhage.*

Theophilus O. Duckworth, *Salt Lake City, Utah; American Medical College, St. Louis, 1905; aged 58; died, July 10, of cerebral hemorrhage.*

Ulysses G. Hoshaw, *Joplin, Mo.; Hospital College of Medicine, Louisville, Ky., 1895; aged 63; died, April 13, of coronary thrombosis.*

John Joseph Lyons, *Troy, N. Y.; Albany Medical College, 1890; aged 70; died, July 1, of chronic myocarditis and chronic interstitial nephritis.*

Henry Floyd Crandall ✠ *Oceanside, Calif.; St. Louis College of Physicians and Surgeons, 1908; aged 57; died, July 16, of angina pectoris.*

Marcus Conrad Hildebrand, *Colusa, Calif.; Chattanooga (Tenn.) Medical College, 1897; aged 63; died, June 10, of pernicious anemia.*

Charles H. Lozar, *Sheridan, Mich.; Detroit College of Medicine, 1901; aged 57; died, June 29, of tuberculosis of the lungs and intestine.*

Caswell Cusick, *Knoxville, Tenn.; Memphis Hospital Medical College, 1898; aged 68; died, June 6, in the Knoxville General Hospital.*

Ezra J. Cobleigh, *Detroit; Michigan College of Medicine and Surgery, Detroit, 1896; aged 60; died, May 30, of acute cardiac dilatation.*

Thomas S. Hollenbeck, *Portageville, Mo.; American Medical College, St. Louis, 1883; aged 79; died, June 11, of diabetes mellitus.*

George Christiansen, *Glendale, Ariz.; Northwestern University Medical School, Chicago, 1911; aged 46; died, July 13, of tuberculosis.*

Alexander Gibson, *Alturas, Calif.; Missouri Medical College, St. Louis, 1889; aged 64; died, June 16, of acute myocarditis.*

Alfred Gifford, *Lawrence, Kan.; St. Louis Medical College, 1878; aged 77; died, May 20, of cardiovascular renal disease.*

William H. Roueche ✠ *Erie, Pa.; Baltimore Medical College, 1895; aged 63; died, July 5, of cerebral hemorrhage.*

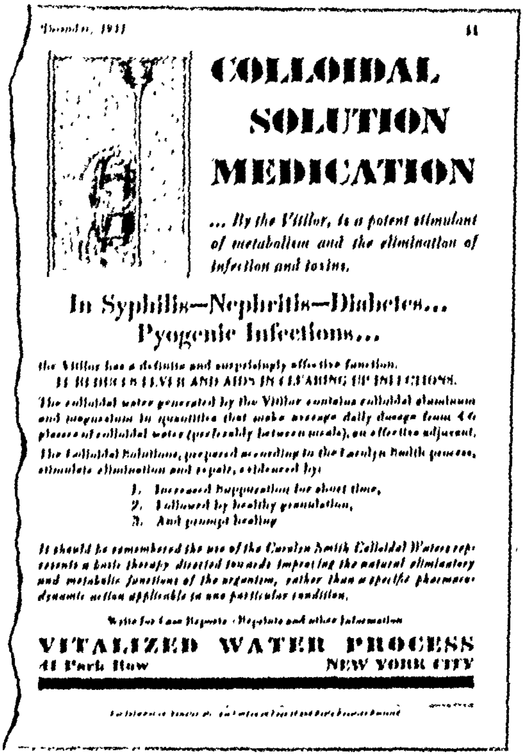
Alonzo Eagon, *Detroit; Grand Rapids Medical College, 1906; aged 70; died, May 4, of angina pectoris.*

Bureau of Investigation

VITALIZED WATER PROCESS COMPANY

The Post Office Authorities Stop Another Attempt to Make a Patent Medicine out of Drinking Water

Some ten years ago—in May, 1922, to be exact—the Bureau of Investigation received its first inquiry regarding the device called the "Vitilor," said to be invented by a Miss Carolyn Scofield Smith and promoted by the Vitalized Water Process Company. The Vitilor is a metallic container through which either distilled water or tap water is passed to emerge containing—alleged—colloid metal in solution. Miss Smith had a book on the subject as well as a number of free advertising leaflets. Her leaflets on "Colloids in Surgical Cases" and "Colloids in Medicine" were delightfully vague and aroused in the technically trained a strong element of suspicion for the claims made by Miss Smith.



December, 1931 11

COLLOIDAL SOLUTION MEDICATION

... By the Vitilor, is a potent stimulant of metabolism and the elimination of infection and toxins.

In Syphilis—Nephritis—Diabetes... Pyogenic Infections...

the Vitilor has a definite and surprisingly effective function.

IT REDUCES FEVER AND AIDS IN CLEARING UP INFECTIONS.

The colloidal water generated by the Vitilor contains colloidal aluminum and magnesium in quantities that make average daily dosage from 4 to 6 glasses of colloidal water (preferably between meals), an effective adjuvant.

The Colloidal Solutions, prepared according to the Carolyn Smith process, stimulate elimination and repair, evidenced by:

1. *Increased Suppuration for short time,*
2. *Followed by healthy granulation,*
3. *And prompt healing*

It should be remembered the use of the Carolyn Smith Colloidal Waters represents a basic therapy directed towards improving the natural eliminatory and metabolic functions of the organism, rather than a specific pharmacodynamic action applicable to one particular condition.

VITALIZED WATER PROCESS
41 Park Row NEW YORK CITY

Photographic facsimile (greatly reduced) of full-page advertisement appearing in American Medicine for December, 1931.

A six page leaflet compiled by Carolyn Scofield Smith and sent out to physicians and others stated, either directly or by implication, that the Vitilor would cure among other things tuberculosis, diabetes, ulcerated teeth, chronic nephritis, pyelitis, asthma, pneumonia, high blood pressure and "water on the knee."

One interesting piece of advertising for the Vitilor was a letter purported to have been written in 1924 by a professor of experimental engineering at a technical school in Brooklyn. The professor was enthusiastic about the Vitilor and especially about colloids in general. According to this letter, the Vitilor produced colloids which were united with oxygen. When water from the Vitilor was consumed by a normal person, the oxygen would not be detached from the colloid and nothing would happen. When, however, the blood reached the part of the body that was diseased, the oxygen would be detached from the colloid, due to the acid condition present, thus, as the letter stated, "causing the acid to break down into water plus a neutral salt, which is eliminated." The professor's letter went on to state that water from the Vitilor was at that time (1924) being used in the Sea View Hospital on Staten Island for tuberculosis and diabetic patients. The letter closed with the statement that "many of my students drink the water and it cures boils, pimples, infected sores, etc."

From 1922 until recently, the Bureau of Investigation has received many inquiries regarding the Vitilor and its inventor. Now come the post office authorities with a fraud order, debarring from the United States mail, the Vitalized Water Company and the Vitalized Water Process and their officers and agencies.

According to a memorandum of the solicitor, the Hon. Horace J. Donnelly, to the Postmaster General, the Vitalized Water Company and the Vitalized Water Process, are owned and operated by Miss Carolyn Smith. Miss Smith is not a physician but claims to have studied chemistry. The Vitilor was described as a tank of about two quarts' capacity, so made that water could be introduced at the bottom through which it was forced through charcoal and then passed through a small screen into and through a chamber containing fine particles of aluminum. The water was drawn out through the top and was to be drunk in doses of from one quarter of a glass to six or eight glasses daily, depending upon the seriousness of the ailments to be treated. The Vitilor sold for $45.00, the cost price, according to the memorandum, being $10.50.

The postal authorities tested one of the Vitilors through the laboratories of the Food and Drug Administration in the Department of Agriculture. The device was there set up and distilled water run through it in accordance with the directions. The amount of metallic residue that was found in the water after passing through the Vitilor was absurdly minute and there was introduced by the government evidence showing that the mineral content of ordinary tap water in various cities is largely in excess of the inconsequential amount added to water that has passed through the Vitilor. The following table shows the aluminum and calcium content of tap water in five cities as compared with the amount of these same metals that would be added by passing it through the Vitilor.

	Milligrams per liter	
	Alumina (Al_2O_3)	Calcium (Ca)
Vitilor water	1.5	29.
Baltimore tap water	4.	18.
Detroit tap water	2.	27.
Harrisburg, Pa., tap water	1.	14.
Springfield, Ill., tap water	10.	50.
Youngstown, Ohio, tap water	3.	49.

The government also presented evidence to show the various foods included in the daily diet contained more aluminum and calcium than is to be obtained by treatment of water with the Vitilor. It is interesting in this connection to note that Miss Smith's device was recommended in the treatment of cancer. The interest lies in the fact that while Miss Smith is recommending aluminum salts in the treatment of cancer, there is a group of rather vocal faddists (together with some quacks) which has, during the past few years, been advancing the thesis that aluminum cooking utensils are the cause of cancer! The solicitor's memorandum concludes with these words:

> "Uncontroverted expert medical testimony in this case shows that the various diseases and ailments claimed to be benefited, cured or prevented by drinking the quantities of water passed through the 'Vitilor' as prescribed by the respondent will in no instance be benefited. When it is considered that the very metals claimed to be added by the 'Vitilor,' both in colloidal and other forms, are daily consumed in food and drink in amounts in excess of the amounts obtained through this device the absurdity of the claims of respondent are manifest.
>
> "The evidence before me shows and I so find that this is a scheme for obtaining money through the mails by means of false and fraudulent pretenses, representations and promises.
>
> "I therefore recommend that a fraud order be issued against the Vitalized Water Company and Vitalized Water Process, and their officers and agents as such, at New York, New York."

The fraud order was issued July 6, 1932.

The Father of Medicine.—Hippocrates was primarily a physician, endowed with remarkable powers of observation and with an unusual store of common sense.—Major, R. H.: Classic Descriptions of Disease, Springfield, Ill., Charles C. Thomas, 1932, page 5.

EXTRAPANCREATIC (CELLULAR) INSULIN

To the Editor:—I would beg the privilege to differ from the conclusions of the Toronto investigators that "there is no evidence that any tissue other than pancreatic either produces or stores insulin." Your editorial on the alleged distribution of insulin (THE JOURNAL, June 25, p. 2291) calls attention to the intricacies of the most modern extraction methods. Tests for insulin are not chemical but biologic, calling for the averaging of results from a large number of mice. You have pointed out that past experiments on plant tissues were inconclusive, and the critics generally agree that this whole question should be reopened: I agree with them but do not agree with the Toronto investigators who practically close the question when they say "there is no evidence." I think that there is evidence, and plenty of it, of the physiologic action of extrapancreatic insulin, to be found in the metabolic data of Soskin, in his various experiments on depancreatized dogs (Tuttle, G. H.: *New England J. Med.* **206**:8 [Jan. 7] 1932). The evidence from extraction is at most negative evidence, whereas that from metabolic data is positive evidence of the physiologic action of some kind of insulin. One reason at least for the failure to extract tissue insulin is the following: The insulin of the pancreas as produced by the cells of the islands of Langerhans is a chemical entity capable of crystallization by the method of Abel. The tissue insulin, of which there is evidence through metabolic data, is impossible of extraction by present known methods, and hence its chemical form is not known; but one thing is practically certain, that the two insulins are not chemically identical since one is produced and activated in the originating cell, where it performs its function, whereas the pancreatic insulin is produced within the pancreas in an inactive state and does not become activated until it leaves the pancreas, which is plainly shown by the strictly scientific experiments of A. H. Clarke (*Johns Hopkins Hosp. Rep.*, 1916). Briefly summarized, these show that if the normal pancreas is perfused with Locke's solution containing physiologic amounts of dextrose, no sugar disappears from the solution. (Plenty of insulin in the pancreas, but in an inactive state.) When the heart was perfused with this solution, the same amount of dextrose disappeared as when normal blood flowed through it. In the next experiment the solution was first perfused through the pancreas (from which it absorbs inactive pancreatic insulin) and then passed through the heart. In this last test from ten to thirty times as much dextrose disappeared in the heart, showing that much inactive insulin was taken up by the solution while passing through the pancreas, and that this insulin became activated while passing through the heart, causing dextrose to disappear. In other words, the insulin that is produced in the pancreas, as well as commercial insulin, is inactive insulin capable of crystallization and of extraction; while the tissue insulin is active insulin, incapable of extraction *as yet*, or of crystallization, but clearly demonstrable by metabolic data furnished by Soskin's (*J. Nutrition* **3**:99 [Sept.] 1930) series of experiments on depancreatized dogs, examples of which I will briefly describe. By old methods such dogs survived for only a week or ten days; by modern methods they may be kept alive indefinitely. The present method of preparing an experimental dog is to remove the pancreas by operation and then to give insulin and raw pancreas until carbohydrate metabolism returns to normal. After this, insulin and pancreas are withdrawn and the dog becomes diabetic. If he is allowed to continue diabetic on a protein and fat diet only, he will live from three to six weeks in favorable cases; but if he is fed a small amount (15 Gm.) of raw pancreas each day, in addition, he will live for several months; or if he is given lecithin daily after the method of Soskin (*Biochem. J.* **23**:1385, 1929) he will live a year or more, and it is believed that dogs can be made to live indefinitely under lecithin No insulin is given Now these facts seem to me to show not only that cellular (or tissue) insulin exists in the dog after depancreatization, but that it has the power of increasing to such an extent as to compensate completely for the loss of the pancreatic insulin Many organs of the body employ this method of compensation But since the compensation develops slowly, and the respiratory quotient in Soskin's cases does not begin to rise from 0 70 or thereabouts until from ten to fourteen days after withdrawal of insulin, one more reason for the failure of the Toronto investigators to secure cellular insulin is apparent, as they killed their dogs after only five days, and since only small quantities of cellular insulin are necessary while the powerful sugar oxidizing action of pancreatic insulin is in operation, only small amounts are normally present in the cells, but on removal of the pancreas this amount increases slowly but effectively until it can be shown from the data of Soskin's tables that about 60 per cent of the carbohydrates of the food still continue to be metabolized after the removal of the pancreas and its insulin At present there is no known way by which sugar can be oxidized and glycogen formed for the continued action of the heart, respiratory and other muscles for a period of a year or more, except by our present known system of carbohydrate metabolism, of which insulin in some form is an essential part, so that until some new system of carbohydrate metabolism not requiring the assistance of insulin, which will furnish vital energy to these dogs and keep them alive for a year or more, is clearly demonstrated, I claim that the existence of other insulin than the pancreatic in the body cannot be denied, even though present methods of extraction fail to show it More than thirty years elapsed after Minkowski's discovery before Banting finally was successful in extracting pancreatic insulin

IRRATIONAL MIXTURES FOR SPINAL ANESTHESIA AND PEPTIC ULCER

To the Editor —Protest should be entered against the apparently commercialized exploitation of the various unscientific and irrational mixtures proposed by George B Pitkin, M D, of Bergenfield, N J A few courageous workers were bold enough to call attention to the irrational mixture containing procaine, starch and strychnine proposed for 'controlled spinal anesthesia" and exploited under the trademarked name of "Spinocaine" by the H A Metz Laboratories, Inc

Recently Dr Pitkin proposed another irrational mixture of protein, lipoids and emetine, for intravenous injection in the treatment of peptic ulcer Dr Pitkin's report on this mixture was grossly uncritical, the exact composition of the mixture was not stated although meticulous directions for its administration were given, and it is obvious that whatever beneficial results were claimed in the report were due to the admitted use of what was essentially a Sippy diet along with this extraordinary intravenous medication The H A Metz Laboratories, Inc, have now the temerity to exploit this irrational and dangerous mixture under the trademarked name of "Synodal (brand of emetabol)"

Ordinarily such a matter as this would merit on the part of scientific medicine only the silence with which "Spinocaine" was received The inclusion of strychnine in a material designed for subarachnoid injection is open to serious objection on the grounds of possible danger unless the strychnine is present in homeopathic doses, when its inclusion in the mixture can only suggest an excuse for a proprietary interest The inclusion of emetine in a preparation proposed for the intravenous treatment of such a condition as peptic ulcer is open also to serious objection on the grounds of possible danger unless the emetine is present only in homeopathic doses, when its inclusion in the mixture would also suggest merely an excuse for trademark or patent purposes Emetine is well recognized as a powerfully toxic alkaloid very slowly excreted from the body, apparently cumulative in action, and particularly dangerous for cardiac muscle It would seem that a word of caution to physicians generally who may be led astray by the extraordinary exploitation of the work of Dr Pitkin would be in order at this time, if only to inhibit the extension of his activities into still more dangerous fields

TULAREMIA AND PARINAUD'S DISEASE

To the Editor —Tularemia in Sweden is the subject of an editorial comment in The Journal, August 13, page 567, the last sentence of which I would like to question, i e, "He states that many cases which had been diagnosed Parinaud's disease were later proved to be cases of 'conjunctivitis tularensis'"

My objection relates to the use of the word "proved," which should have been "assumed," especially since Granstrom does not go so far as to say that it is proved

I have given considerable attention to testing the serums of cases of Parinaud's disease, especially from the New York clinics, and I have never found one that agglutinated Bacterium tularense

OVARIAN EXTRACT IN HEMOPHILIA

To the Editor —In De Lee's 'Principles and Practice of Obstetrics" third edition, page 11, line 10, is the following statement 'Ovarian extract reduces the coagulability of the blood and reduces blood pressure ' In The Journal, April 23, Foord and Dysart report the treatment of a case of hemophilia by ovarian extract The statements seem contradictory Please explain

M D, California

Answer —The third edition of De Lee's "Principles and Practice of Obstetrics" was published in 1921 This was before the work of Allen, Doisy, Pratt, Zodek and others on the female sex hormone and the sex hormone of the anterior pituitary In the fourth edition the sentence quoted is omitted, although the paragraph remains practically unchanged

The rationale for the treatment of hemophilia by the use of ovarian extract is based on the sex linked transmission of the disease Hemophilia occurs only in males, while it is transmitted through the female Although the female transmits the disease to her sons, she shows no manifestation of the disease If the female can transmit the disease she must potentially have the disease and there must be something in the female mechanism that masks its presence The greatest difference between males and females is the sex organs, and the ovary is the most important of the female sex organs Whole ovarian preparations have given encouraging results in the treatment of hemophilia

When theelin, lutein and several preparations of whole ovary are added to normal blood in a test tube, the clotting time of the blood is not materially changed When these substances are added to hemophilic blood in a test tube, the clotting time of the blood is decreased These substances do not reduce the coagulation time of hemophilic blood to normal but do decrease it to from one half to one fourth of the time of the control The action here seems to be on the blood platelets, by decreasing the resistance of the platelets, the clotting of hemophilic blood is hastened

In the sixth edition of Dr Williams' book on Obstetrics, published in 1931, the following statement is made "Menstrual blood contains fewer red cells and more lymphocytes than the circulating blood and according to Schickele, and Stickel and Zondek, the absence of coagulation is due to substance formed in the uterine tissue, as the fluid expressed from the uterus under pressure inhibits coagulation when added to normal blood."

The work on sex hormones is young and the part they play in the entire body mechanism is far from understood.

SYPHILIS IN PREGNANCY

To the Editor:—In March, a young married woman, aged 21, came to my office complaining of pain on the left side, simulating pleurisy. Examination disclosed the presence of mucous patches in the throat and on the vaginal mucous membrane. The patient was two months pregnant. The Wassermann reaction was four plus, which was confirmed by a subsequent blood test. After taking three injections of 0.2 Gm. of water soluble bismuth and two injections of 0.45 Gm. each of neoarsphenamine, the patient refused further treatment. She has returned at the present time and the blood Wassermann reaction now is negative. The pregnancy has continued without any untoward events. In the meantime, there has developed a systolic murmur over the apex, loud and blowing, but no apparent enlargement of the heart. The blood pressure is 102 systolic and 40 diastolic. How do you account for the negative Wassermann reaction in view of such a small amount of treatment, and how should treatment be directed from this period on? Please omit name.

M.D., Ohio.

Answer.—The pregnant state may have something to do with the change to a negative Wassermann reaction after the small amount of treatment. The chemical and physical changes that take place in the blood of pregnant women may influence the Wassermann reaction and for this reason some obstetricians do not believe that the Wassermann reaction is as reliable in gestation as in the nonpregnant state. However, most syphilologists place as much reliance on the test in pregnancy as at other times. Another possible explanation for the rapid change to a negative test is that syphilis may affect women to a milder degree than men.

In spite of the negative Wassermann reaction, the patient should be treated intensively not alone for her own sake but for the benefit of the unborn child as well. Syphilis is transmitted from the mother to the fetus through the placenta. This usually takes place after the fourth or fifth month of gestation, and unless treatment is instituted at this time and continued throughout gestation, the child may be born afflicted with syphilis. The more thorough the treatment, the greater the chances for a living and healthy child. After delivery, even if the child is apparently healthy, Wassermann tests should be repeatedly taken on both mother and child for many months. A roentgenogram of the baby's long bones may be of assistance if syphilis is present. If the blood tests or the roentgenograms are positive, further treatment is, of course, to be given to both mother and child.

The systolic murmur perhaps has no especial significance, because such murmurs are common during pregnancy. However, the heart should be reexamined from time to time and it is important to check up on the patient's blood count. If anemia is present, this should be treated by means of diet, liver extract and iron and arsenic preparations.

NITROHYDROCHLORIC ACID IN HAY FEVER

To the Editor:—Beckman, in his "Treatment in General Practice," advocates the use of 10 minims of aqua regia, or concentrated nitrohydrochloric acid, to be taken by mouth, well diluted with water, four times a day, in allergic states, especially hay fever. What is the rationale of this treatment? If, as Beckman claims, the allergic individual "is at all times in a state of relative alkalosis," is aqua regia the best substance to counteract it? What are the dangers? Kindly omit name.

M.D., Mineola, Long Island, N. Y.

Answer.—About a year and a half ago, Beckman offered the suggestion (The Journal, Nov. 22, 1930) that there may be an intimate relationship between acid-base balance and the allergic state, but he has subsequently on several occasions refused to discuss further the matter either in addresses or in print, because of his stated belief that much harm can come of the reiteration of hypotheses unsubstantiated by experimental studies. It is therefore not strictly correct to say that he "claims" that the allergic individual is at all times in a state of relative alkalosis, but only that he has drawn the attention of the profession to the fact that this point of view merits investigation; with this position many students of the matter are heartily in agreement. On purely empirical grounds, however, the nitrohydrochloric acid treatment of hay fever, as revived by Beckman, continues to be advocated by him; its rationale is still unexplained, the sole warrant for its use seeming to be the success obtained in a certain proportion of cases. It is not thought that the remedy, if used in the manner advocated, is in any wise dangerous, as it has been used for other purposes, and in variable dosage, by several generations of physicians.

TREATMENT OF UNDULANT FEVER

To the Editor:—My brother has had Malta fever for the past year. At first he was bedfast but last fall I started giving him Malta fever vaccine, made by the National Drug Company. This keeps his fever down and he is up and able to work as long as he takes a cubic centimeter of the vaccine, about every three days. As soon as he stops the vaccine his temperature begins to rise. Do you think he will wear out the disease as long as he is not permitted to have fever? Some seem to think that he will have the disease forever unless his fever is allowed to take its natural course. He is in fine condition. His weight is 196 pounds (89 Kg.), which is normal. He is quite strong but tires easily. He was given some severe reactions last fall but these did not change the course of the disease any. He has had neoarsphenamine and mercurochrome-220 soluble intravenously. Perhaps it would be interesting to know that he can take 50 grains (3.25 Gm.) of quinine a day and not even know it, as far as tolerance is concerned. Also is there anything else I can do for him? His age is 27.

C. Dryden Baird, M.D., Eureka, Kan.

Answer.—Recovery is achieved gradually in the vast majority of cases of undulant fever. As the patient in question is young and apparently in good physical condition, it is believed that the outlook is favorable for recovery. A few cases have continued over a period of years. In such cases it is well to search thoroughly, by physical examination, for evidence of localized infections, and, if found, surgical procedures may be invoked. Brucella infection has been found in the gallbladder and in ovarian lesions and it probably may localize in various lymph nodes, particularly the retroperitoneal glands. Rest in bed during the febrile period and for a reasonable time after the temperature becomes normal offers greater hope of complete recovery at an earlier date than other management.

PARKINSON SYNDROME AFTER ENCEPHALITIS

To the Editor:—Please outline the latest treatment for Parkinson syndrome (involving left hand and forearm only), vertical nystagmus and mental depression, all following epidemic encephalitis six years ago. What is the prognosis in a woman, aged 26? Has hyoscyamus been proved to be of value? Please omit name and address.

M.D., New York.

Answer. — The outlook for recovery in such a case is extremely poor, but the condition may become stationary and not shorten life materially. The most useful drugs are scopolamine hydrobromide, stramonium and atropine, but in a given case one cannot tell which drug will do the best without giving each a trial of some weeks.

TREATMENT OF AMEBIASIS AND SYPHILIS

To the Editor:—A woman, aged 62, is a chronic carrier of Amoeba histolytica. One son, aged 28 years, has amebic colitis. Both show Amoeba histolytica on their stool examination and have for years. A second son, aged 38 years, has attacks of acute abdominal cramps with stools containing mucus and blood, but his stools show no Amoeba histolytica on repeated microscopic examinations. He acquired active syphilis eleven weeks before seeking medical advice. At this time he presented florid secondaries with a four plus Wassermann and a positive Kahn reaction. Four injections of 0.9 Gm. of neoarsphenamine produced an exfoliative dermatitis. Intravenous injections of 1 per cent mercuric cyanide or mercuric oxycyanide solution produce eructations of gas and abdominal cramps, with passage of mucus and blood in stools which show no amebas. Please advise as to treatment. Please omit name.

M.D., California.

Answer.—The woman, aged 62, and the son, aged 28, might well be given chiniofon-N. N. R. (see New and Nonofficial Remedies, 1932, p. 125) or carbarsone (The Journal, Jan. 16, 1932, p. 230) in the recommended dosage of 0.25 Gm. in gelatin capsules twice daily after meals for ten days, in a total dosage of 5 Gm. The latter drug is in the experimental stage. Preceding this treatment, urinalysis and a phenolsulphonphthalein test should be done to exclude liver or kidney conditions which would make the use of arsenic undesirable. After a free interval of ten days to allow for excretion, the treatment could be repeated if cysts reappear.

The second son, aged 38, presumably has also an amebic infection, although the entire colitis may be syphilitic. Careful examination of fresh stools, both for cysts and for trophozoites, should be combined with sigmoidoscopic examination and search for amebas in deep scrapings. A systematic review of the causes of dysentery ought to decide the etiologic diagnosis.

It is not stated whether or not the colitis and dysentery preceded the syphilitic infection. Certainly arsenicals must be avoided in earlier treatment. The phenolsulphonphthalein test and urinalysis should be watched repeatedly. If amebas are present, emetin hydrochloride should be given, 0.03 Gm., hypodermically, one dose daily for ten days, unless contraindicated by serious fall in blood pressure or increase of dysentery. At the same time, one daily retention enema of 200 cc. of 1 per cent chiniofon-N. N. R. should be given. The direct treatment of the syphilis might be continued cautiously with iodobismitol (ampules 2 cc.) Squibb, one-half ampule per dose with two free days between for two doses, and then a full ampule on each third day to a full course of ten injections (Hanzlik, P. J.; Mehrtens, H. G.; Gurchot, Charles, and Johnson, C. C.: Iodobismitol, The Journal, February 13, p. 537). Further treatment would have to be planned in the light of the clinical course.

PAIN AFTER INTERCOURSE

To the Editor.—A married woman, aged 44, height 5 feet 4 inches (162 cm.), weight 168 pounds (76 Kg.), always healthy and well except for painful menstruations, has been treated by having the cervix dilated, but without relief. She was married in 1917 and in 1920 was delivered of a normal child by high forceps extraction. She sustained a third degree tear, which was repaired, and then mild sepsis developed, with good recovery. Thereafter she began to have attacks of pain simulating appendicitis and was operated on in 1924. A suppurating appendix was removed; there was pus in the fimbria or the right tube, which was drained, several small cysts were removed from the right ovary and a trachelorrhaphy and perineorrhaphy was done. Recovery was uneventful and health has been excellent since, except for constipation. The menstruations have been regular, only moderately painful and normal in color. She has no vaginal discharge. The entire physical examination shows her to be an apparently sound, normal woman. However, she has had one symptom ever since the operation that has refused to respond to any kind of treatment. Immediately after sexual intercourse she has a severe, deep pelvic pain on the right side, of an intense aching character, lasting from twenty to thirty minutes, and slightly relieved by pressure and heat. Her libido is normal, and she has no aversion to the sexual act and has a normal orgasm. She has no pain unless she experiences the orgasm. The act itself causes her no distress. Can you advise me of anything I can do in this case? Both she and her husband are anxious for her to be relieved. Please do not publish name.

M. D., Iowa.

Answer.—It is almost certain that the anatomic changes brought about by the operation are responsible for the pain experienced by the patient. However, it is not easy to explain the mechanism by which the pain is produced unless there are large palpable and visible scars in the vault of the vagina or unless the vaginal vault is markedly constricted. Since the discomfort is present only when the woman experiences an orgasm, the sudden disappearance of intense vascular congestion most likely plays a part. Perhaps one or more sensory nerve ends were included in some of the sutures at the time of operation and these are affected by the enormous engorgement of blood that occurs in the surrounding tissue during intercourse and the sharp withdrawal of blood after an orgasm. Treatment should be conservative and should consist of repeated gentle dilation of the vagina, especially the upper part, with glass or other dilators.

PREECLAMPTIC TOXEMIA

To the Editor.—A nullipara seven months pregnant, in good physical condition and everything normal, within ten days of examination returned with epigastric pain, failing sight in both eyes and a blood pressure of 170/100, which had previously been 124/75 constantly. I sent the patient home to bed on a nonnitrogenous diet. Within twenty four hours the blood pressure rose to 220/120 and the patient complained of an excruciating generalized headache. She was taken to the hospital immediately and placed on a strict Stroganoff regimen. During the first twelve hours the patient rallied. The blood pressure dropped to 175/100 and then began to rise. Venesection was performed, 750 cc. of blood being drawn without avail. The blood pressure rose to 230/125 and the head was "bursting." The epigastric pain was not complained of. At this time a classic cesarean section was performed, the child being a normal, three pound girl, who died after fourteen hours. The mother progressed nicely. The headache left in about twelve hours but was considerably alleviated shortly after the patient awoke from her ethylene anesthetic. After six weeks the blood pressure has gradually dropped to 135/100 and the eyesight in that time has returned, completely at times, but for the most part it is not normal as yet, though the patient can read ordinary print for short periods. An ophthalmologist has been following the eyes from the start of the trouble and he thought the eye trouble was due to retinal hemorrhages. At this time he thinks that the sight will return almost if not completely. Kindly give me an opinion on this case. Is the blood pressure usually this slow in returning to normal or will it return completely? What should be the interpretation of the diastolic pressure in this case or one like it? The fluid intake and output was in good proportion throughout this trouble even at its peak, although the urine was extremely turbid with albumin with the heat test. There were no casts. Would a kidney function test have been of any avail or help here? Please omit name.

M.D., Illinois.

Answer.—This was a case of acute preeclamptic toxemia and the treatment carried out was correct, except in one essential. Local anesthesia should have been used for the cesarean section rather than ethylene, because it has been shown that all inhalation anesthetics may be injurious to women who have any of the toxemias of pregnancy. The ophthalmologist is correct in his prognosis because the eyesight is nearly always restored to normal after a few weeks or months. It is impossible to predict whether and when the blood pressure will return to normal even in the cases in which there is absolutely no clinical or laboratory evidence of permanent injury to the kidneys. The diastolic pressure is of great importance. Judging from the clinical course in this case there is at least a 60 per cent chance that both the systolic and the diastolic pressure will return to normal in due time. It frequently happens that normal women have a mild hypertension and even a mild albuminuria six weeks after delivery. On the other hand, occasionally women with nephritis have a normal blood pressure and urine at this time. Renal function tests performed during pregnancy or the early puerperium are not a reliable guide as to whether or not the patient has definite nephritis and will have permanent renal injury. Unless there is outspoken evidence of a true nephritis it is best to defer the final diagnosis until four months after delivery, although the clinical diagnosis made at the time a patient is discharged from the hospital is usually correct. Peckham and Stout (*Bull. Johns Hopkins Hosp.* **49**:225 [Oct.] 1931) examined a large series of women who had toxemia, excluding eclampsia and excessive vomiting, and they found that 40 per cent had a definite chronic nephritis from four months to four years after delivery.

DANGERS OF DUSTS IN RAYON PLANTS

To the Editor.—A manufacturing plant deals with a process during which the atmosphere of the work room is filled with a fine lint known as floc, made up of ground cotton and rayon. This floc is often composed of ground material that has been dyed. Outside of the hazard one would expect from inhalation of atmosphere permeated by cotton fibers, what industrial hazard could be expected in addition, owing to the fact that these fibers have been dyed? Is there danger of lead, arsenic or aniline intoxication following the inhalation of this floc, assuming, of course, that the dyes contain these chemicals?

A. D. Lazenby, M.D., Baltimore.

Answer.—Vegetable dusts taken into the lungs are essentially harmless, except as they may lead to allergic states.

The old term "bysinosis," descriptive of a pneumonoconiotic state due to cotton dusts, is without practical importance. No dusts long entering the respiratory tract are wholly innocuous, but if the hazards from silica dust are placed at 100, those from cotton are not more than 5.

Dust from unmodified rayon is not at this time regarded as harmful. Certain artificial silks may now be weighted with lead or other toxic agents. If so, hazards may arise.

This query assumes that lead, arsenic and aniline are contained in the dyes coloring the dust particles. Accepting this, actuality of hazards will depend solely on the quantity of these agents reaching the lungs. Less than a milligram, daily reaching the lungs, of any one of the three, is capable of inducing harm. The daily intake of a milligram of a combination of the three may bring about a "mixed intoxication." However, it may be observed that many finished aniline dyes are harmless; that the quantity of arsenic or lead may be below the threshold of harm.

It may prove advantageous to determine the quantity of dust, by weight, in a given volume of air, and near the same time determine the quantity of lead and arsenic in a representative sample of collected dust.

AMEBIASIS CUTIS

To the Editor.—I would appreciate a discussion of the accepted treatment and the precautions in preparing the patient for treatment in a case of amebiasis cutis. If emetine is suggested, please state who prepares ampules for intravenous medication, and state precautions and dosage. Some time ago an article appeared in The Journal stating that extirpation of the diseased areas was the best and most positive procedure. Will you please give your opinion? Please omit name.

M. D., California.

Answer.—Amebiasis cutis, an ulceration of the skin due to Endamoeba histolytica, was first described by Engman and Heithaus (*J. Cutan. Dis.* **37**:715 [Nov.] 1919). The diagnosis must be confirmed by finding motile amebas in fresh preparations from lesions of the skin or by fixed smears and sections of tissue. The ulceration usually involves the skin and deeper tissues of the abdominal wall and is characterized by rapid spread, an irregular border, a dusky red advancing halo beyond the margin of the ulcer, pain and extreme tenderness on pressure, and indolent granulation tissue forming the floor of the ulcer. Two cases were recently reported by Engman and Meleney (*Arch. Dermat. & Syph.* **24**:1 [July] 1931) in which the ulcerations developed following a resection of the colon and after drainage of an amebic abscess of the liver, both of which were fatal

Emetine hydrochloride is the accepted treatment, either subcutaneously or intravenously in daily doses of from one-third to 1 grain (0 02 to 0 065 Gm) but should not be given for more than eight days on account of the danger of cumulative action Serious toxic reactions have been reported, such as vomiting diarrhea, abdominal pain, peripheral neuritis, acute nephritis hemoptysis, collapse and death Most of the manufacturers prepare ampules for intravenous injection

Extirpation, preferably with the electrocautery, might be undertaken in the early stage of the ulceration to prevent its spread

NAMES OF BARBITAL COMPOUNDS

To the Editor —In The Journal, June 4, on page 1994, ten or twelve lines from the top, occur the words "pentobarbital, amytal, phenobarbital pernocton and sodium barbital " I cannot find an accurate definition in my books of these term, nor does the druggist know them I should like to know their trade names and synonyms lest I confuse them in prescribing

M D , Palmyra, Mo

Answer —New and Nonofficial Remedies, issued by the Council on Pharmacy and Chemistry, contains descriptions of Pentobarbital-Sodium (pentobarbital is not marketed as such only as the sodium salt), Amytal, Phenobarbital and Barbital Sodium Phenobarbital is official in the U S Pharmacopeia Sodium Barbital is a synonym for Barbital Soluble U S P It is strange that a pharmacist would not keep in his possession the latest Pharmacopeia in order to be able to recognize official preparations New and Nonofficial Remedies would be serviceable to both the pharmacist and the correspondent

Pernocton is stated to be a 10 per cent solution of the sodium salt of the secondary butyl-beta-bromallyl barbituric acid The Council on Pharmacy and Chemistry has declared Pernocton not acceptable for New and Nonofficial Remedies for lack of critical evidence that routine intravenous injection of potent narcotics is desirable or safe (The Journal, Oct 3, 1931, p 1001)

A list of the better known barbital derivatives and the trade names of some was given in one of the series of articles on the "Indispensable Use of Narcotics" (Chemistry of Barbital and Its Derivatives, The Journal, May 30, 1931, p 1869)

ASTRINGENT EFFECTS ON MUCOUS MEMBRANES

To the Editor —Kindly advise me what, if any, other drug has the same action on mucous membrane as solutions of silver nitrate I mean its discoloration of skin and fabric, and its bad effect on the plating of instruments Will a solution of zinc chloride produce the same results? If not, can you suggest some other drug that will? Please omit name

M D , Illinois

Answer —The action on mucous membrane of silver nitrate solutions is dependent chiefly on the astringent qualities of these solutions While there is some antiseptic quality, this may in a large part be considered negligible In view of the disagreeable qualities of silver nitrate, other astringents may be used Zinc chloride is among them So, too, are solutions of antipyrine from 0 5 to 1 per cent strength Copper sulphate may also be used topically in strengths of from 1 to 2 per cent For irrigation, as in the nose, strengths of 1 2 000 to 1 3 000 are better borne

DOSAGE OF SCARLET FEVER TOXIN FOR IMMUNIZATION

To the Editor —Immunization of adults against scarlet fever is successful when 500, 2,000, 8,000, 25,000 and 80,000 skin test doses of scarlet fever toxin at weekly intervals are given to known Dick positive persons Will you please tell me the corresponding dosages for children of 2, 4 and 6 years of age? Please omit name

M D , Chicago

Answer —The dosage of scarlet fever toxin employed for immunizing children 2, 4 and 6 years of age is the same as that employed for immunizing adults

TREATMENT OF BUBO

To the Editor —Allow me to ask what is the recognized treatment for unilateral bubo after suppuration has taken place Please omit name

M D , California

Answer —The recognized treatment for unilateral bubo after suppuration has taken place is incision and drainage

Book Notices

The Wisdom of the Body. By Walter B Cannon, M D, Sc D, LL D, George Higginson Professor of Physiology, Harvard Medical School Cloth Price, $3 50 Pp 312, with 41 illustrations New York. W W Norton & Company, Inc, 1932

Dr. Cannon's views on homeostasis have been repeatedly considered in the editorial columns of The Journal. There are within the human body numerous stabilizing devices tending to maintain and to restore normality. There is an automatic mechanism for maintaining a constant supply of water, salt, sugar, proteins and fat. There are, moreover, factors of safety and of defense, as well as mechanisms for repair Most of the chapters of Dr Cannon's book concern these mechanisms as they are involved in relationship to specific substances. His concluding chapter indicates similar forces in biology and in social life. The living human organism suggests that stability is of prime importance Thus it teaches a lesson to the social organism. The volume represents a sound and philosophical summary of human physiology

Entstehung, Erkennung und Behandlung innerer Krankheiten. Band I: Die Entstehung innerer Krankheiten: Pathologische Physiologie. Von Dr. Ludolf Krehl Fourteenth edition Paper Price, 39 60 marks Pp 716 Berlin F C W Vogel, 1932

The previous edition of Krehl's volume on clinical pathology was published two years ago as the center piece of a treatise on principles for the practice of internal medicine Since then the second part has been published. Although the finished textbook that has been promised by the author has not yet become available, a new edition of its first portion has been necessary to meet the steady demand for this standard book However, physicians have been accustomed for years to new editions of this clinical pathology The habit became well rooted probably before the ultimate destiny of the volume as one segment of a larger work was foreseen by the author And now its new title is also becoming familiar. In this new, thorough and conscientious revision the long experience of Professor Krehl in such tasks is conspicuous There are no radical changes anywhere, in fact, they are not numerous, and are spread out quite evenly in the different chapters As usual, they consist of brief conservative references to and comments on recent investigations and modified opinions.

An Introduction to Dermatology. By Richard L Sutton, M D, Sc D LL D, Professor of Diseases of the Skin, University of Kansas School of Medicine, and Richard L Sutton, Jr, A M, M D, Visiting Dermatologist to the Kansas City General Hospital Cloth Price, $5 Pp 565, with 183 illustrations St Louis C. V Mosby Company, 1932

This is virtually a condensed form of the eighth edition of Sutton's "Diseases of the Skin" Intended primarily for students, it should well serve that purpose It is rich in good illustrations, is well indexed, and is concise and clear The format is excellent; to each of the conditions more rarely encountered, the authors devote a short paragraph. The disorders of common occurrence are more fully and adequately considered. The treatment recommended is rational and the prescriptions are simple and of a kind that can be readily dispensed. The first part of the book is devoted to the principles of dermatology, anatomy, physiology, pathology, etiology and treatment, and includes also a topographic classification which should be of service to the student. Newer subjects, such as allergy and bacteriophage therapy, are included The book is a sound, conservative work that should serve as a useful introduction to dermatology.

Pathologie und Therapie der Erkrankungen des Kehlkopfes, der Luftröhre und der Bronchien. Von Prof Dr. M. Hajek, Vorstand der Universitätsklinik für Kehlkopf-, Nasen- und Ohrenkrankheiten in Wien Abteilung II Paper Price, 60 marks. Pp 193-432, with 123 illustrations Leipzig · Curt Kabitzsch, 1932.

The second section of this work, the first portion of which was reviewed recently, continues in the middle of a sentence of the previous section in the chapter on the differential diagnosis of diphtheria. The condition of the pharynx, larynx and trachea in other acute diseases, such as typhoid, influenza and glanders, is described in detail. An interesting chapter is devoted to diseases of the larynx and treachea with their various dermatoses. This is followed by a complete section on tuberculosis of the upper air passages. Then follow topics such as syphilis, leprosy and rhinoscleroma The section on the injury of the larynx, trachea and bronchi is followed by a fairly complete chapter on foreign bodies in the respiratory tract as well as the treatment of stenoses of the larynx, trachea and bronchi It is in the chapter on disturbances of innervation of the larynx that this volume ends in the middle of a sentence in the same manner as occurred in the first section. The arrival of the third and final section is anticipated with much pleasure in view of the fact that the second section shows the same high standard of print and illustrations as did the first.

The Art of Being a Woman. By Olga Knopf Edited by Alan Porter. Cloth Price, $3 Pp 307 Boston Little, Brown & Company, 1932

The background of this book is training in medicine, physiology and adlerian psychology. The book begins with a brief survey of woman's position in society through the ages and particularly the importance of the inferiority complex in an earlier day. The second part is an analysis of adolescents in which incidentally there comes a consideration of the causes of prostitution, with which, however, few authorities will agree. The author takes it for granted that the initial motive is a desire for pleasure and the secondary motive a desire to make money. The book is rather opposed to prohibition, feeling that it makes indulgence in liquor a goal. There are also considerations of homosexuality and its causes. The reasons for failure of most women to marry are given most careful consideration, and also the factors underlying marriage. The points are covered again in the section on sexual adaptation and on the married woman The concluding chapters of the book deal with the elderly woman, women in industry and the means of explaining sex to children. The volume concludes with a plea to women to stop suffering with an inferiority complex and to think they are equals of men, independent and cooperative, even if they are not. Few American women will need this advice

Vaccination préventive de la tuberculose de l'homme et des animaux par le B C G. Rapports et documents provenant des divers pays (la France exceptée) transmis à l'Institut Pasteur en 1932 Paper Pp 366 Paris Masson & Cie, 1932

This volume opens with a reiteration of previous statements on the harmlessness of B C G, supported by citations of numerous official endorsements by scientific societies and congresses during the last four years. A summary of reports of animal experiments and clinical experience up to 1932 is presented Recent experience in guinea-pigs, rabbits and monkeys on the whole supports the original claims of Calmette and his associates on successful preventive inoculation in these animals. Reports of equal success in the vaccination of cattle in several countries are given Chief opposition to the method is found in North America Calmette attributes this opposition largely to the organization of the tuberculosis eradication campaign on this continent, which is based on the tuberculin test. Widespread use of B C G in cattle and the consequent artificial production of reactors would prove confusing. Calmette feels that, successful as the campaign has been in this country, a revision of the method, to include vaccination, would be advantageous Up to 1932 about a million children had been vaccinated, about two thirds of them in France or the French colonies. About 400 necropsy protocols, a surprisingly small number in so large a vaccinated group, appear to be on record. These indicate no progressive lesions from the B C G, although in numerous cases the organism could be isolated from lymph nodes. Some remarkable cases of accidental overdosage or intentional large dosage in congenital defectives, without harm, are reported. A final summary is presented of the mortality in 443,656 children in 46 countries outside of France, indicating a death rate of 7.9 per cent in the vaccinated and 15.3 per cent in the nonvaccinated in the first year of life. To an unbiased reader the argument for the harmlessness of the method seems convincing. Variation in the selection of material, however, still makes an evaluation of the success of the method as a preventive procedure difficult to make.

Law and Literature and Other Essays and Addresses. By Benjamin N. Cardozo, Chief Judge of the Court of Appeals of New York. Cloth. Price, $2.75. Pp. 190. New York: Harcourt, Brace & Company, 1931.

The newly appointed member of the Supreme Court of the United States has made available in book form a number of essays on various subjects, mostly related to law. Of most interest to the physican is the essay entitled "What Medicine Can Do for Law." It indicates a thorough appreciation of the nature of scientific evidence and of the fact that the medical profession of this country is best fitted to supply such evidence in the medical field. Judge Cardozo is inclined to believe that the teachings of biochemists, of psychiatrists and of penologists will transform our whole system of punishment for crime at no distant day. He also finds a necessity for study and education of the criminal. He feels the need for reform in the determination of insanity and points out that this reform must come in legislation rather than in court procedure.

Archiv und Atlas der normalen und pathologischen Anatomie in typischen Röntgenbildern. Die gesunde und kranke Wirbelsäule im Röntgenbild: Pathologisch-anatomische Untersuchungen. Von Geh. Med.-Rat Prof. Dr. Georg Schmorl. Für die Röntgenkunde bearbeitet von Dr. med. Herbert Junghanns. Fortschritte auf dem Gebiete der Röntgenstrahlen, Ergänzungsband XLIII. Herausgegeben von Prof. Dr. Grashey. Paper. Price, 30 marks. Pp. 211, with 345 illustrations. Leipzig: Georg Thieme, 1932.

This is a monograph on the pathologic anatomy of the vertebral column, presented with an extensive bibliography. The illustrations emphasize especially the developmental defects encountered in the spinal column. Phases of the intervertebral disk are dealt with at length. The vast amount of anatomic material at the disposal of Dr. Schmorl and the variety of lesions described in such an authoritative manner make the monograph invaluable to all interested in spine lesions, especially the roentgenologist and the orthopedic surgeon.

The Home Nurse's Handbook of Practical Nursing: A Manual for Use in Home Nursing Classes in Young Women's Christian Associations, in Schools for Girls and Young Women, and a Working Text-Book for Mothers, "Practical" Nurses, Trained Attendants, and All Who Have the Responsibility of the Home Care of the Sick. By Charlotte A. Aikens, R.N. Fifth edition. Cloth. Price, $2. Pp. 331, with illustrations. Philadelphia: W. B. Saunders Company, 1931.

This volume has passed through five editions and numerous reprintings, probably because it is one of the most practical books in this field. It is, furthermore, a thorough consideration of its subject. It includes not only numerous hints on preventive medicine but a great deal of helpful material on the care of the sickroom, care of the invalid, dietetics, methods of giving remedies, bandaging, first aid, and nursing in general. The illustrations unfortunately have not been as carefully revised as has the text. There is not the slightest reason for showing home nurses Peyer's patches or the appearance of a culture of tubercle bacilli. The majority of the pictures are, however, attractive.

A Bibliography of the Honourable Robert Boyle, Fellow of the Royal Society. By John F. Fulton, M.A. Paper. Pp. 172, with a portrait. Oxford: University Press, 1932.

This compilation of the writings of Boyle can be of interest solely to the special student who is willing to undertake the formidable task of assessing Boyle's scientific achievements. The main body of the volume lists chronologically not only the appearance of the various books but also the various editions of these books, location of the copies, and facsimiles of the title pages. In each case the history of the book and the nature of its more important contents are indicated. This volume was certainly a herculean task involving, figuratively speaking, an infinite number of hours of the most patient type of scholarly labor—surely an all-absorbing occupation which few real scholars possess. Having erected the solid foundations for the scientific evaluation of Boyle's scientific career, the author might well make the scientific assay, for no one else is better qualified to do so.

The Lame, the Halt, and the Blind: The Vital Rôle of Medicine in the History of Civilization. By Howard W. Haggard, M.D., Associate Professor of Applied Physiology, Yale University. Cloth. Price, $4. Pp. 420, with 200 illustrations. New York & London: Harper & Brothers, 1932.

Most of the essays in this book were prepared by the author for the Medical Division of the Eastman Kodak Company and presented by him over the radio during the Eastman Hour. The essays touch every aspect of medicine from an historical point of view and are likewise related to current trends, since many of the notions of the past are in the credulities of the present. The book is handsomely illustrated with numerous historical items and has an exceedingly good index. For collateral reading in medicine, it is delightful. If any criticism at all is to be made of the book, it is for the lack of any orderly arrangement or system to bind the essays together.

The Cambridge Medical School: A Biographical History. By Sir Humphry Davy Rolleston, Bart., G.C.V.O., K.C.B., M.D., Regius Professor of Physic in the University of Cambridge. Cloth. Price, $5. Pp. 235, with 21 portraits. Cambridge: University Press, 1932.

This book contains an interesting account of Cambridge in its vicissitudes and its glory, giving a description of the medical school from its beginning to the present day. The various departments (anatomy, physiology, biochemistry, experimental psychology, pathology, biology, physic) are taken up in separate chapters. There are portraits of those who added much to the glory of the institution, including such men as Caius, Heberden, Sir Michael Foster, Langley, Gaskell, Roy, Kanthack, Woodhead, Clobery, Glisson, Paget and Allbutt.

Twenty-Five Years: A Memorial Volume in Commemoration of the Twenty-Fifth Anniversary of the Vineland Laboratory, 1906-1931. Edited by Edgar A. Doll, Ph.D., Director of Research. Series 1932, No. 2. Fabrikoid. Pp. 135. Vineland, N. J.: Training School at Vineland, New Jersey, Department of Research, 1932.

This book is published in commemoration of the twenty-fifth year celebration of the establishment of the Vineland Laboratory and School for Training of the Feeble-Minded. It includes the addresses delivered on that occasion, with a record of the personnel and publications since the institution was established. The essays include, among others, contributions by Gesell on "The Study of Genetic Psychology," by Edgar A. Doll on "The Outlook for Further Research," and by Earl Barnes on "Child Research and Social Progress."

Landois' Lehrbuch der Physiologie des Menschen, mit besonderer Berücksichtigung der praktischen Medizin. Bearbeitet von Dr. med., Dr. phil. h. c. R. Rosemann, o. ö. Professor der Physiologie und Direktor des Physiologischen Instituts der Westfälischen Wilhelms-Universität zu Münster. Twentieth edition. Paper. Price, 22.50 marks. Pp. 850, with 168 illustrations and one portrait. Berlin: Urban & Schwarzenberg, 1932.

The nineteenth edition of this book was reviewed in THE JOURNAL, Jan. 4, 1930, page 56. Aside from an eight page increment, the plan and execution are the same as in the previous edition. Valuable as a scientific textbook, it may be recommended particularly to physicians and graduate students of medicine who desire to read with profit while reviewing their knowledge of German.

Poems of Science. By William Pallister, B.A., M.D., C.M. Cloth. Price, $2.50. Pp. 248, with 17 illustrations. New York: Playford Press, 1931.

The author of this volume studied physics, bacteriology and pathology under competent teachers. His volume is a combination of essays and poems on the nature of things, on man and the stars, and on many other scientific subjects. The poems prove quite perfectly that scientific diction does not lend itself easily to poetical manipulation.

The Structure of Insanity: A Study in Phylopathology. By Trigant Burrow, M.D., Ph.D. (Psyche Miniatures, General Series No. 40). Boards. Price, 2/6. Pp. 80. London: Kegan Paul, Trench, Trubner & Company, Ltd., 1932.

This essay presents Dr. Burrow's views on the social relationships of insanity and the necessity for studying the morphologic data involved in the distortion of man's attention as a social process.

Medicolegal

Patient's Wealth and Physician's Fee

(Glenn v. Thompson (Mo.), 45 S. W. (2d) 948)

The plaintiff removed the defendant's prostate gland and attended him over a period of forty-one days, never visiting him less than twice a day and often three and four times a day. He rendered a bill for $1,050. The defendant thought $500 a sufficient fee, paid that amount, and the plaintiff sued him for the balance. The trial court excluded testimony tending to show the defendant's financial ability to pay and, at the request of the defendant, charged the jury as follows

> The court instructs the jury that the financial ability or inability of the defendant to pay plaintiff the reasonable value of the services cannot be considered by the jury or taken into consideration in determining the reasonable value of such services as the jury may find under the evidence were rendered defendant by the plaintiff

The jury returned a verdict for the defendant, and the plaintiff appealed to the St. Louis court of appeals

In excluding evidence as to the defendant's wealth and in instructing the jury as it did, the trial court erred, said the appellate court. A usage and custom in the profession, in fixing the fee for an operation, to give some consideration to the ability of the patient to pay, was testified to by witnesses both for the plaintiff and for the defendant, said the court That fact, therefore, must have been in the contemplation of the parties when the service was rendered, and necessarily must be one of the elements to be considered on a trial which proceeded on that theory Furthermore, witnesses for the defendant testified that a reduction in fee is generally made in case a patient is unable, financially, to pay the usual fee Evidence of the defendant's wealth was admissible, therefore, to show that he was not entitled to such a reduction The defendant's family physician, who referred the defendant to the plaintiff, in testifying for the defendant, admitted that the practice of physicians was to charge varying fees for the same class of operations, and that the charge for an operation such as the *one* involved in this case varies from nothing to $3,500, depending somewhat on the ability of the patient to pay. This physician, said the court, must have realized that his patient was in a critical condition and that immediate attention by a skilled surgeon was essential He must have known, continued the court, that the case was one that justified the risk of a higher charge by a surgeon of known skill and must have had some idea as to the defendant's ability to pay for the kind of service he was seeking For error committed by the trial court in refusing to admit evidence as to the financial ability of the defendant to pay the fee charged and in instructing the jury as it did, the judgment in favor of the defendant was reversed and the case remanded

Abdominal Pregnancy, Accident and Therapeutic Abortion.—The appellee, Mrs Sieber, was injured in an accident, September 8 She was operated on, October 17, and an abdominal pregnancy of three months' duration was discovered In a suit against the appellee, Abend, she contended, among other things, that by reason of the accident she was caused to "suffer a miscarriage" The trial court gave judgment for Mrs Sieber, and Abend appealed to the Court of Appeals of Maryland There was no evidence, said the court, that the accident had anything to do with the abortion and none to show that an abortion would not have been necessary even if the accident had not occurred at all. When an injury for which damage is claimed, in this case an operation for extra-uterine pregnancy, follows in point of time the accident for which suit is brought, and the subsequent development usually has its peculiar and independent cause, then the original accident as the exciting cause of the ultimate effect must be affirmatively shown. This was not done in this case. When disease or infection is set in motion or aggravated by injury or when the accident may be followed by disease or injury as its cause, damages may be recovered for such unexpected results, but in every instance proof of such facts is required and nothing is assumed The proof of the effect of the accident on the extra-uterine pregnancy was a matter, the court said, to be testified to by one skilled in medicine or surgery. No such witness testified. The judgment of the trial court, in favor of Mrs. Sieber, was therefore reversed and the case remanded for a new trial.—*Abend v. Sieber (Md.), 158 A. 63.*

Expert Testimony Based on Roentgenogram Not in Evidence.—In proceedings before the Oklahoma Industrial Commission, a physician testified that he had taken a roentgenogram of the claimant's spinal column. The roentgenogram was not offered in evidence but the physician was permitted, over the objection of the employer and his insurance carrier, to testify as to the condition indicated by the roentgenogram The roentgenogram, said the Supreme Court of Oklahoma, was the best evidence as to what it indicated. Ordinarily a roentgenogram must be explained or interpreted by a medical expert The witness was competent to do so, but the employer and his insurance carrier were entitled to examine the roentgenogram for the purpose of cross-examining the witness, and, if they so desired, were entitled to submit it to other experts for interpretation. The physician should not have been permitted to testify unless the roentgenogram was offered in evidence or some proper reason given why it could not have been produced —*Patrick & Tillman v. Matkin (Okla.), 7 P. (2d) 414.*

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to The Journal in continental United States and Canada for a period of three days Issues of periodicals are kept on file for a period of five years only Requests for issues of earlier date cannot be *filled* Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested) Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order Reprints as a rule are the property of authors and can be obtained for permanent possession only from them

Titles marked with an asterisk (*) are abstracted below

American Journal of Diseases of Children, Chicago

43: 1433 1653 (June) 1932

*Respiratory Failure in Poliomyelitis Treatment with Drinker Respirator J L Wilson, Boston —p 1433

*Seasonal Variation in Antirachitic Action of Arkansas Sunshine P L Day, Little Rock, Ark —p 1455

*Treatment of Congenital Syphilis with Acetarsone (Stovarsol) Given by Mouth C H Maxwell, Jr, Auburn, N Y, and J Glaser, Rochester, N Y —p 1461

Psychic Enuresis in Normal Children Experimental Study J M Lewis and J Ostroff, New York —p 1490

*Adenoids and Immunity H B Lemere, Los Angeles —p 1494

Study of Effects of Ultraviolet Irradiation on Group of Preschool Children Preliminary Report Helen Dudley Bull, G H Maughan and Ethel B Waring, Ithaca, N Y —p 1502

*Antirachitic Value of Milk from Cows Fed Irradiated Yeast E T Wyman and A M Butler, Boston —p 1509

Study of Water and Mineral Balances in Epileptic Children I Effects of Diuresis, Catharsis, Phenobarbital Therapy and Water Storage I McQuarrie, Minneapolis, and R C Manchester and Clara Husted, Rochester, N Y —p 1519

Respiratory Metabolism in Infancy and in Childhood XIV Effect of Thyroid Therapy on Metabolism of Protein in Normal Infants L E Weymuller, Brooklyn, T C Wyatt, Syracuse, N Y, and S Z Levine, New York, with technical assistance of M Kelly —p 1544

Ganglioneuroma Report of Two Cases with Review of Literature J A Bigler and A Hoyne, Chicago —p 1552

Respiratory Failure in Poliomyelitis.—Wilson reports that in six children suffering from poliomyelitis who had paralysis of the intercostal muscles and the diaphragm without complications (such as pneumonia), the Drinker respirator was efficient in maintaining pulmonary ventilation for long periods A therapeutic trial of the respirator seems desirable as soon as possible after any reduction of the vital capacity is discovered which is due to weakness of the respiratory muscles Marked dyspnea or cyanosis should not be awaited as indications for initiation of treatment The action of the respirator seemed very effective in two children with bulbar paralysis without intercostal involvement who had a sudden complete cessation of respiration after choking The use of the machine seemed sometimes helpful but was often entirely ineffective in nine children with bulbar paralysis, without intercostal involvement, who had a disturbed central control of respiration manifested by irregular breathing Only two of these nine children lived The use of the machine in cases of bulbar paralysis without intercostal involvement is not recommended except as an emergency and after every attempt has been made to free the pharynx from secretions It was not always possible to foretell accurately the effectiveness of the respirator before therapeutic trial Except for moderate emphysema found at necropsy in three patients with bulbar paralysis, no evidence of harm due to the use of the machine was discovered

Antirachitic Action of Sunshine.—Day made biologic determinations of the antirachitic action of sunshine at Little Rock at all times of the year with large groups of animals under carefully controlled conditions The average daily amount of sunshine necessary to afford the same partial protection against rickets in rats receiving a rachitic diet varied from 5 minutes in May, June and July to 168 minutes in December, with intermediate values for the other months

Treatment of Congenital Syphilis with Acetarsone.—Maxwell and Glaser state that acetarsone probably has a definite place in the treatment for congenital syphilis That the drug cannot be used indiscriminately, as the reports from some foreign clinics might be interpreted to suggest, is amply demonstrated by the one fatality and the toxic manifestations that occurred in the authors' small series The advantages of the oral treatment for congenital syphilis over the methods usually employed are evident However, the exact position that acetarsone should occupy in the treatment for congenital syphilis, at least as far as this country is concerned, remains yet to be determined by those who have at their disposal sufficient clinical material for the study this drug deserves, and sufficient interest to follow their cases carefully, so that there will be a minimum of danger to the patients

Adenoids and Immunity.—Lemere calls attention to the fact that the adenoid is a physiologic and lymphatic structure with a definite form and admirably designed to expose the greatest possible lymphatic surface as a barrier to the entrance of nasal infection through the nasopharyngeal mucosa into the general circulation He reports that in a series of more than 300 children the adenoids were left at the time the tonsils were removed *Daily expulsive blowing exercises were insisted on* as after-treatment Nasal breathing improved, colds and sinus symptoms and acute and chronic aural conditions were less frequent

Pasteurized Yeast Milk.—Because of the possibility of difference in the specific factors *in viosterol and milk from cows* fed irradiated yeast and because there are certain advantages in the inclusion of the antirachitic factor in the food of infants rather than adding it as a separate therapeutic agent, Wyman and Butler studied the effectiveness of such "yeast milk" in the healing of active rickets in children They found that the special pasteurized yeast milk was an effective source of antirachitic substance as determined by its ability to cause healing in advanced active rickets in infants and advanced chronic rickets in children After five minutes' boiling, the milk still possessed antirachitic properties The administration of antirachitic vitamin in so palatable a form and in a food so essential and generally used as milk would seem to have certain advantages

*Streptococci in Blood in Rheumatic Fever, Rheumatoid Arthritis and Other Diseases Based on Study of Five Thousand Two Hundred and Thirty Three Consecutive Blood Cultures S S Lichtman and L Gross, New York —p 1078

Treatment of Cardiovascular Syphilis.—Moore and his associates present a general consideration of the subject of the treatment of cardiovascular syphilis, based on 53 patients with aortic aneurysm and 112 with aortic regurgitation In 20 of the 165 patients, the aneurysm or the aortic regurgitation had not caused symptoms and was accidentally discovered during routine physical examination The onset of symptoms was usually abrupt but sometimes was slow and insidious. All except 13 of the 165 patients in this series had been subjected to the strain of hard physical labor. The most frequent association with other lesions of syphilis was that with syphilis of the central nervous system (especially tabes dorsalis), which occurred in from 17 to 18 per cent of the patients. An additional 17 per cent of patients with cardiovascular syphilis, but without clinical evidence of neurosyphilis, had abnormal spinal fluids. The actual incidence of complicating neurosyphilis was thus about 35 per cent. Positive Wassermann reactions of the blood were obtained for 98 per cent of the patients with aneurysm and 96 per cent of those with aortic regurgitation. One hundred and forty-seven (89 per cent) of the patients had never received any treatment for syphilis before the development of cardiovascular syphilis. Of the remainder, not one had received adequate treatment for early syphilis. Only 4 of the 165 had received arsphenamine at the time of early syphilis, and none of these got more than three injections. These data constitute a powerful argument for the adequate treatment of early syphilis. They also indicate that modern antisyphilitic treatment is probably not responsible for the apparent increase in the incidence of syphilitic aortitis. From the analysis of their material, the authors conclude that properly supervised antisyphilitic treatment, with adequate general medical care, given to patients with aneurysm or aortic regurgitation, prolongs life, alleviates symptoms, maintains the ability to pursue a gainful occupation and reduces the period of incapacity.

Relationship of Pancreatic Insufficiency to Pernicious Anemia.—According to Cheney and Niemand, the present conception of Addison-Biermer anemia is that it is a deficiency disease due to an inadequate supply of a protein derivative necessary to normal maturation of red blood cells. As a result of successful experiments in feeding beef digested with normal human gastric contents to patients with Addison-Biermer anemia, Castle has concluded that the cause of the disorder is dependent on the gastric achylia. The nature of this supposed gastric defect has remained unproved, and he has termed it the unknown intrinsic factor. Recent studies of the gastric contents during fasting and duodenal contents strongly suggest that in cases of Addison-Biermer anemia there is a marked insufficiency of the pancreatic enzymes, notably trypsin, in addition to the gastric achylia. The macrocytosis characteristic of this anemia has also been frequently observed in pancreatic disorders. Feeding experiments performed by the authors, in which solutions of trypsin were used to digest beef, failed to produce any effect on the blood changes in cases of Addison-Biermer anemia. Feeding experiments in which an artificial gastric content containing hydrochloric acid, pepsin and trypsin was used to digest beef in three instances in two cases of Addison-Biermer anemia and in one instance in a case of sprue with a similar blood picture produced changes in the red blood cell count, hemoglobin determinations and reticulocyte response similar to those obtained by Castle. Changes in the average diameter of the red cells characteristic of a beginning remission after liver therapy occurred in these four instances and also in two others when very small amounts of trypsin were used. No other evidence of improvement in the blood changes was detected in the last two cases. The authors' feeding experiments show that beef digested by hydrochloric acid, pepsin and trypsin yields the erythrocytic maturation factor necessary to produce all the blood changes characteristic of a remission in pernicious anemia. The changes demonstrated are not as pronounced as those in adequate liver therapy but are on the whole more like those in inadequate treatment with liver. It seems probable that the protein derivative deficiency in Addison-Biermer anemia is due to a lack of both peptic and tryptic digestion. Trypsin would then represent the unknown intrinsic factor of Castle.

Thiocyanate Therapy in Hypertension.—Goldring and Chasis present data on fifty patients with hypertension subjected to seventy-four trials with thiocyanate therapy. In forty-six of these patients it was associated with chronic diffuse glomerulonephritis. Forty-four trials were made in the outpatient clinic and thirty with the patients confined to the hospital. Observations were made on the daily excretion rate of thiocyanate in the urine and the number of days necessary for its complete elimination after continuous medication and after a single dose in patients with essential hypertension and nephritic hypertension and in normal persons. Toxic effects of thiocyanate were not observed in four patients with chronic diffuse glomerulonephritis, three of whom responded by a satisfactory fall in blood pressure. Therapeutic, toxic or fatal effects could not be anticipated from the amount of the drug administered. The dosage found to be most effective in lowering blood pressure and least often attended by toxic manifestations was 0.326 Gm. (5 grains) given daily over a period of from fourteen to seventy-eight days. Thiocyanate was 31 per cent effective in lowering blood pressure in this series. Toxic manifestation occurred in thirteen patients, or 17 per cent, of the total group studied.

Absorption of Iodine from Gastro-Intestinal Tract.—Cohn reports studies on the rate of absorption of free iodine in aqueous solution, of diluted compound solution of iodine and of potassium iodide and potassium iodate from the gastro-intestinal tract of the dog. These studies show that the iodine is converted to iodide before it is absorbed. If these studies are applicable to the human being, they would seem to refute the assertion that compound solution of iodine is more beneficial than potassium or sodium iodide in controlling the high basal metabolism of exophthalmic goiter, since, when compound solution of iodine is used, the percentage of iodine absorption is no greater than when potassium or sodium iodide is administered.

Use of Urea in Cardiac Dropsy.—Urea administered in massive doses according to a method described by Miller and Feldman was found to be an effective diuretic over long periods of time in selected cases of cardiac dropsy. Whereas it can function alone over many months in keeping the patient edema-free, it may require the supplemental use of other diuretics. This is true for the patient with or without auricular fibrillation. Cases are reported in which its unbroken administration continued over three years. Urea does not impair the function of the kidneys or alter their histologic structure after prolonged administration. Once the signs of congestive heart failure have been removed, urea is valuable in preventing their recurrence. The drug tends to maintain the patient's weight at a low and constant edema-free level over months and even years. During such periods, the authors' patients often required little or no restrictions of the intake of fluid or salt within ordinary dietary limits.

Pancreatic Extract in Angina Pectoris and Intermittent Claudication.—An insulin-free extract of the pancreas, a vasodilator that modifies the pressor effects of epinephrine and dilates the coronary arteries of the rabbit's heart to a degree exceeding that produced by drugs of the purine group, was administered intramuscularly by Nuzum and Elliot to twenty patients with angina pectoris. Two, or 10 per cent, were not helped, five, or 25 per cent, were somewhat relieved, eleven, or 55 per cent, were greatly helped, and two who were benefited by treatment died later. Forty-one patients with angina pectoris who received the usual medical treatment and were followed for a like period were studied as a control series. In ten instances, or 24.3 per cent, no benefit was observed, fourteen patients, or 34.1 per cent, experienced moderate relief, fourteen received pronounced benefit, and three, or 7.4 per cent, died. Five patients with intermittent claudication, one with thrombo-angiitis obliterans and one with cerebral vascular spasms and angina pectoris were benefited in a pronounced degree by treatment with the extract.

Streptococci in Blood in Rheumatic Fever.—In a study of 5,233 consecutive blood cultures in a general hospital, Lichtman and Gross found that with adequately sensitive methods an incidence of nonhemolytic streptococcemia (alpha and gamma types) between 4 and 15.5 per cent with an average of 6 + per cent occurs in at least nine diseases, i. e., acute rheumatic fever with polyarthritis, chronic rheumatic cardiovascular disease, rheumatoid arthritis, aplastic anemia, pernicious anemia, leukemia, colitis, meningococcus meningitis and pyelitis and pyelonephritis. On the basis of the incidence of the "transient" streptococcemia alone, these organisms cannot justifiably be considered as the causative agents of these diseases.

Correction of Ptosis and Epicanthus.—Blair and his associates say that, in the absence of any action of the levator palpebrae muscle, the patient is apt to attain some elevation of the paralyzed lid by overaction of the occipitofrontalis muscle. This suggested that a direct fixation of the tarsus of the upper lid to the occipitofrontalis muscle would give much better elevation of the lid than does the simple continuity of the somewhat fixed tissues of the brow. Various plans have been proposed for doing this, but it is the authors' belief that the most satisfactory is the direct connection by means of a live tendon cut from autogenous tissue. For this purpose they have used thin strips of fascia lata, which will give permanent live and approximately natural connective tissue fixation. Even when previously inactive, this extra load may stimulate a lagging occipitofrontalis muscle to increased movement. Because congenital ptosis and epicanthus may occur in the same case, and the scar contraction that causes a traumatic epicanthus may also prevent proper elevation of the lid, the correction of epicanthus is considered with that of ptosis. Correction in the congenital type can usually be obtained by flap switching that adds vertical length at the expense of the transverse redundancy. In the traumatic type it may be necessary to use a skin graft or switch a flap from a distant site. Elevating a flat nasal bridge will help in appropriate cases.

Orbital Tumors.—Samuels presents a brief pathologic review of some of the tumors of the retrobulbar space, the so-called concealed tumors, including those of the optic nerve, all of which sooner or later produce exophthalmos. Attention is drawn more particularly to the manner in which the preexisting structures react to the presence of tumors rather than to the morphology of the tumors themselves. The theme is presented in the form of clinical cases that have yielded anatomic material for study.

Anterior Chamber Punctures in Relation to Intra-Ocular Tension.—Abraham states that animal and human experimental data on the effects of anterior chamber punctures are in agreement. This includes the changes in intra-ocular tension following withdrawal of the aqueous. The usual reaction of a normal eye to a withdrawal of the aqueous would be hyperemia, particularly of the ciliary body, and hypertonia. Hypotonia may result following withdrawal of the aqueous if the eye shows subnormal function, as in atrophies and amblyopia, or if the ciliary body is decreased in activity, as by atropine. In cases of primary glaucoma, intra-ocular tension following anterior chamber puncture and withdrawal of the aqueous may be higher than before puncture, may be lower than before puncture, though above normal, or may show no pathologic tension. In cases of secondary glaucoma the same condition may be present. No inflammatory or glaucomatous process seems necessary to obtain a high tension following withdrawal of the aqueous, even when no previous high tensions have been present. The hypertonia in normal eyes following anterior puncture may be as high as that found in pathologic conditions.

Postoperative Care Without Bandages.—According to Rabkin, a number of ophthalmologic clinics and hospitals in America and Europe are using simplified ocular dressings. This tendency may eventually lead to the use of the open method. In no case has there been any complication that could be attributed to the use of the open method. Indeed, there are certain advantages. The postoperative period is usually shorter and the patient more comfortable. No trauma of the eye has been observed, and the author does not believe it to be more frequent in the open method, if the patient has been sufficiently instructed. Apparently, the character of the bacterial flora is unchanged in the open method. Control and observation of the wound are easier, and time and work are saved. The author believes that this method deserves more consideration from ophthalmologists in general.

Osteomyelitis of Skull and Nasal Accessory Sinus Disease.—Wilensky discusses the cases of osteomyelitis of the skull that are found to complicate acute and chronic disease of the nasal accessory sinuses. He considers only cases due to infection by the ordinary pyogenic bacteria. The clinical picture presented by the majority of these cases is similar. The infection that leads to the fatal result is usually postoperative and occurs within two or three days after an operation for disease of the nasal accessory sinuses. The diploe of the frontal bone is invaded by the organisms, and an osteomyelitis is set up. The infection spreads, on the one hand, through the outer table, giving rise to subperiosteal abscesses beneath the scalp; it passes inward, on the other hand, and may subsequently give rise to extradural or subdural abscess, general meningitis, cerebral abscess or a thrombosis of the longitudinal or other large sinuses. The dura mater is affected in practically all cases, and the pachymeningitis may remain localized a long time. Thrombosis occurs chiefly in the lateral or longitudinal sinuses. The invasion of a large venous sinus is often manifested by emboli with distant metastases. Pneumonia and bronchopneumonia occur frequently. It is generally easy to make a diagnosis of osteomyelitis in the bones near the orbit or ear. However, it is often difficult to recognize the diffuse form because the general symptoms are often more pronounced and may mask the local symptoms. A diagnosis can be made before operation from a careful study of the symptoms that accompany the sinusitis or mastoiditis. It is necessary to operate when the osteomyelitis becomes evident, and the operation should be as extensive as possible. The cranial bones should be resected beyond the limits of the lesion. If the wound continues to granulate and if the temperature remains high, sequestrums are present and they must be removed as completely as possible. There is a large mortality. The patient succumbs to one or more of these conditions with or without the manifestations of a general blood infection, as evidenced by the presence or absence of a positive blood culture, after a varying number of weeks or months ranging to one or more years.

Intratracheal Inhalation Anesthesia.—Flagg describes the technic of intratracheal inhalation anesthesia that he has used as a routine method in the last four years. In his hands, trauma has not followed this technic. He believes that this absence of trauma has been partly due to each of the following factors: adequate ether relaxation, elimination of preliminary medication (morphine and atropine), adequate exposure, lubrication of the tube and the use of a mouth gag when intubating. In this technic, adequate suction must always be available for the best results. In order to reduce the irritability and the diameter of the intubated element, a pharyngeal gauze pack is preferred to an intratracheal balloon. Irritation is caused by the pharyngeal pack unless care and lubrication are employed in placing it. Experience has shown that the cough spasm following intubation may readily be controlled and its effects promptly met. The technic of intratracheal inhalation provides a functioning equipment for artificial respiration in the case of respiratory failure. Routine cocainization was avoided, ether relaxation being employed instead. While any anesthetic agent may be employed, ether is the anesthetic of choice in the majority of cases. The opinion appears to be that intubation carried out in the manner prescribed by the author does not predispose to laryngeal tuberculosis in a case presenting pulmonary tuberculosis, and that the presence of the intratracheal tube through the facilities afforded for suction of the trachea provides one of the most efficient means of reducing postoperative morbidity in thoracic operations. It has been found that the method is indicated in all operations on the head and neck, and in any condition in which aspiration is to be avoided.

Pins at Periphery of Lung.—The Jacksons call attention to the fact that pins at the periphery of the lung are practically always lodged head downward. This may be due to the catching of the point and the tumbling over of the head end, and partly to the fact that the head end is the heavier. The primary cause of pins in the lungs is carelessness in putting pins in the mouth. The secondary etiologic factors are numerous. The cause of the pin reaching the periphery is a pawl and ratchet-like action of the pin; the head is free to move downward during inspiratory elongation of the bronchi, and the point catches and resists upward movement during the bronchial shortening of expiration and coughing. The limit of downward travel is the smallest bronchus that the head of the pin can enter. After the initial choking, gagging and coughing there is, in the case of pins at the periphery of the lung, a symptomless interval of a number of months. Sooner or later, however, suppurative changes, with productive coughing and progressively increasing impairment of health, supervene, and a fatal ending may eventually occur if the pin is not removed. All pins at the periphery of the middle and lower lobes and descending branches of the upper lobes can be removed through the mouth by peroral costophrenic bronchoscopy. The ascending branches of the upper lobes present great difficulties, but fortunately their invasion by pins is exceedingly rare.

Origin and Antiquity of Syphilis: Evidence from Diseased Bones: Review, with Some New Material from America. R. U. Williams, Buffalo.—p. 931.

Tumors of Muscle Type.—According to Cohen, the incidence of muscle tumors varies with the type. Leiomyoma occurs frequently, *especially in the uterus. Leiomyosarcoma* is less frequent, according to the author's studies, than is generally claimed. He describes what appears to be the first case of metastasis of leiomyosarcoma to the brain. Rhabdomyoma occurs very rarely. Rhabdomyosarcoma is rare. The diagnosis of muscle tumors depends on close observation of the type of cell; i. e., the finding of spindle-shaped cells arranged in whorl formation or of cross-striations in large, irregular cells. Mallory's and Van Gieson's differential stains are of diagnostic aid.

Experimental Thrombo-Angiitis Obliterans. — Horton and Dorsey obtained acutely inflamed veins and arteries at biopsy or at amputation of extremities in thirty-four cases of thrombo-angiitis obliterans. Gram-positive, pleomorphic streptococci were obtained in pure culture in nine cases and green-producing streptococci in two. Cultures were taken in a similar manner of arteries and veins from ten amputated extremities of patients with arteriosclerosis, and five cultures yielded gram-positive, pleomorphic streptococci. Cultures from normal arteries and veins of twenty-four other patients were negative. Four different methods were used in attempting to reproduce thrombo-angiitis obliterans in experimental animals: 1. Pleomorphic streptococci were injected intravenously into thirteen rabbits. Intimal proliferation with thrombosis took place in two. Thirty-one rabbits were given injections in a similar manner with organisms obtained from extracted teeth, tonsils, the nasopharynx and secretions of the prostate. Negative results were obtained. 2. Pleomorphic streptococci were injected into the femoral muscles, adjacent to the femoral vessels, of forty-two rabbits. Intimal proliferation and thrombosis occurred in ten rabbits. 3. Portions of the vessels obtained from patients with thrombo-angiitis obliterans were embedded in positions adjacent to the femoral vessels of twenty-nine rabbits and one dog. Intimal proliferation and thrombosis occurred in seven rabbits, and in one rabbit trophic changes and dry gangrene developed in the toes of the hind feet. 4. Vessels that had been previously shown to contain pleomorphic streptococci were embedded into the pulp cavities of teeth of two dogs, with negative results. The results obtained by injecting organisms at sites adjacent to the femoral vessels of rabbits and those obtained by embedding segments of vessels from human beings in positions adjacent to the femoral vessels were essentially the same (23.8 and 24.1 per cent, respectively, positive). The pathologic lesions found in the vessels of these rabbits appeared to be identical with those seen in human beings with thrombo-angiitis obliterans and represent, so far as the authors are aware, the first lesions of this type that have been produced in experimental animals. The study suggests that thrombo-angiitis obliterans is of infectious origin and that the streptococcus may be of etiologic significance.

Color, Volume and Saturation Indexes in Anemias.—Osgood and his associates review the literature on the color, volume and saturation indexes in anemias. They report detailed results, obtained by methods of research accuracy, for hemoglobin, red cell count, cell volume, color index, volume index, and saturation index in 144 cases of anemia and related conditions. The most characteristic change in pernicious anemia is the preponderance of macrocytes in the blood. This is most easily recognized by the volume index determination. The high color index in pernicious anemia is due to the increase in size of the cell, not to increased concentration of hemoglobin within the cell. In other words, the saturation index is normal, and true hyperchromia does not occur either in pernicious anemia or in any other condition so far studied. If either the color or the volume index is above 1.25, the patient with rare exceptions will prove to have pernicious anemia. Such a high color and volume index constitutes a definite indication for the administration of liver therapy. A low saturation index strongly suggests that the anemia is due to chronic blood loss and constitutes a definite indication for a search for the cause of the bleeding, an effort to stop the bleeding, and the administration of iron in large doses. Anemia is rare in patients having malignant tumors without bone marrow metastases, hemorrhage or secondary infection; hence the finding of anemia in such patients should suggest that one or more of these complications has occurred. The color, volume and saturation index determinations are extremely valuable aids in the differential diagnosis of anemias. It is necessary to warn, however, that they may be not only of no assistance but actually misleading if they are not determined by an accurate method with controlled technic and if the calculations are not based on correct normal standards now available instead of on the obsolete values still included in most textbooks.

Size and Hemoglobin Content of Erythrocyte.—Wintrobe calls attention to the fact that the differentiation of pernicious and other forms of macrocytic anemia and of anemias characterized by microcytosis and hypochromia from other forms of anemia is not only of academic and diagnostic interest but also essential in the guidance of appropriate treatment. Such differentiation is best made, from the standpoint of simplicity and accuracy, by the calculation of the volume and hemoglobin content of the red corpuscles. These calculations, when combined with the simple examination of the blood smear, yield more information at the expense of much less effort than is entailed in the measurement of the diameter of the red corpuscles. It is possible, on the basis of differences in the size and hemoglobin content of the erythrocyte, to distinguish four types of anemia: 1. Macrocytic anemias, characterized by an increase in the mean volume and hemoglobin content of the erythrocytes and represented chiefly by pernicious anemia and many cases of sprue. 2. Normocytic anemias, which are distinguished by the presence of red cells of normal size and hemoglobin content; this group includes cases of anemia resulting from acute blood loss, hemolytic anemias (malaria), and aplastic anemias. 3. Simple microcytic anemias, which are characterized by a moderate reduction in the size of the red cells with no or little reduction in their hemoglobin concentration; in this group are found the majority of the anemias associated with chronic infections and toxic processes. 4. Hypochromic microcytic anemias; in this type of anemia there may be little or no reduction in the red cell count. Nevertheless the red corpuscles are found to be very small and are poorly filled with hemoglobin. The determination of the size and hemoglobin content of erythrocytes is chiefly important in that it makes possible the ready differentiation of the macrocytic and hypochromic microcytic anemias from the other two types.

Clinical Applications of Supravital Staining. — Tompkins analyzes the conditions in which the specific information obtained from supravital staining is likely to be of help in diagnosis or prognosis. She shows that the method is of value, first, in the differentiation of mononuclear cells of various types, including the young forms of the different strains of white blood cells, and secondly, in showing qualitative differences in any single type of mononuclear cell. In the latter respect the method is particularly helpful in depicting qualitative changes in the lymphocytes and monocytes. Therefore, the method is likely to give assistance in any condition involving the mononuclear cells. This is true whether it is a condition involving the lymphocytes or monocytes or a condition associated with the appearance of young cells. In the case of diseases involving the lymphocytes it has been found that the increases in those cells in certain diseases, such as pertussis, lymphocytic reactions to sepsis, and tuberculosis, are due to cells that are normal in every respect, while other diseases are characterized by the appearance of lymphocytes which stain in the manner of young cells. The infections of childhood, typhoid, malaria and measles are the common conditions in which young lymphocytes may be found. On the other hand, the lymphocytes in infectious mononucleosis are different from either normal or young cells. The lymphocytes of lymphatic leukemia have been shown to exhibit characteristic changes in mitochondria, vacuolar apparatus and nuclei which help to differentiate them from other conditions involving the lymphocytes, as well as from other mononuclear cells. Supravital staining has proved especially valuable in diseases involving the monocytes, because it has not only aided in the detection and differentiation of these cells but has revealed sufficiently characteristic changes in them in a number of pathologic conditions (tuberculosis, undulant fever, malaria, hepatic disturbances, pyogenic infections, and conditions associated with anemia) for the modifications to be of value in diagnosis. The diagnosis of a third type of leukemia, i. e., monocytic leukemia, has been made more certain by supravital blood studies. As a result of these studies it has been possible to differentiate the condition accurately from lymphatic and myelogenous leukemia. In fact, in the leukemias in general, supravital staining with the double stains has proved of tremendous value in the separation of the three main types and in the classification of those types according to their chronicity.

*Epilepsy and Congenital Syphilis. K. A. Menninger and W. C. Menninger, Topeka, Kan.—p. 632.

Active External Hydrocephalus.—Gardner describes three cases diagnosed as active external hydrocephalus. This diagnosis was made on the basis of the encephalographic observation of marked dilatation of the subarachnoid spaces over the cerebral hemispheres. The activity of the process was indicated by the symptoms of increased intracranial pressure and choking of the optic disks in each case. The total volume of cerebrospinal fluid was found to be markedly increased, but the cause of this increase was not determined. In each case a simple subtemporal decompression was followed by complete recovery.

Poliomyelitis.—According to Sands, the treatment in acute anterior poliomyelitis should be directed toward neutralization of the virus by intravenous and intramuscular administration of serum from convalescent patients as soon as the diagnosis is made; reduction of cerebral edema by administration of hypertonic solutions of dextrose intravenously, and by spinal drainage; combating difficulties in respiration and in deglutition; and protecting the paralyzed muscles by proper mechanical support. The treatment of the paralyses should be directed by properly trained physicians and by competent nurses trained in orthopedic and physical therapeutic principles. Prophylactic measures during an epidemic may be advantageously utilized by segregating the child, and by the administration of immune serum or whole blood intramuscularly. The latter procedure may be repeated every three or four weeks.

Epilepsy and Congenital Syphilis.—The Menningers state that the literature on the relationship of congenital syphilis and epilepsy contains many opinions and statistical studies. The consensus favors the view that congenital syphilis may be a direct or an indirect cause of the epileptic syndrome; some investigators regard their occurrence together as merely coincidental. The authors feel that much of the published work on this problem is based on inadequate diagnostic data. Sometimes a single fixed criterion of syphilis is selected, such as the serum Wassermann reaction or the therapeutic test (in spite of the well known fallibility of both). Sometimes variable tests are used in various cases without uniformity; sometimes the data on which the diagnosis is based are not stated. Too frequently, case histories are not cited. The crux of the problem is the definite diagnosis or exclusion of congenital syphilis. This the authors do not believe can be done on the basis of the presence or absence of any single symptom or sign or of several fixed and invariable symptoms and signs (*including convulsions*), but *only on the presence or absence* of observations in the carefully investigated hereditary, physical and chemical constituents of the individual which, taken in association, point to such a diagnosis. Using such a standard, they selected for presentation thirty-one cases of individuals having convulsions of the "idiopathic epilepsy" type which were regarded as being of congenital syphilitic etiology. It was concluded that congenital syphilis can produce convulsions, directly and indirectly, without the presence of gross brain lesions or encephalitis (juvenile dementia paralytica) and thus appears to be "idiopathic" epilepsy. From a statistical point of view, when compared with the total number of epileptic persons and the total number of persons with congenital syphilis the occurrence of congenital syphilitic epilepsy must be regarded as unusual. The frequency, however, is not so important as the definite establishment of its occurrence.

*Bronchiectasis. H. Ballon, J. J. Singer and E. A. Graham, St. Louis.—p. 502.
New Portable Pneumothorax Machine. J. J. Singer, St. Louis.—p. 562.

Acute Empyema.—According to Heuer, the respiratory infections that commonly give rise to empyema may roughly be divided into two large groups, pneumonia and influenza. Their clinical manifestations, their pathologic changes and their mortality differ from one another and, in each group, differ from year to year. So, too, do the manifestations of the empyemas that complicate them often differ. In lobar pneumonia the empyema usually follows the disease, appearing after the pneumonic process has subsided; in influenza, it usually appears coincidentally with the pneumonic process. There is therefore a difference in the time of appearance of the empyema with respect to the pneumonic process in the lungs, a circumstance which has an important bearing on the treatment of empyema. The symptoms in the two groups of cases may vary greatly. In empyema following pneumonia they are often comparatively mild. The patient may indeed have a distressing cough, a septic temperature and unpleasant sweats and may lose weight; but in an uncomplicated pneumococcic empyema he may live on for months until he is overcome by mediastinal pressure symptoms or some accident. In empyema following influenza the symptoms are often far more severe; a high grade of toxemia, rapidity of the pulse, urgent respiration and the general appearance of the patient all suggest that he is desperately ill. Indeed, his symptoms seem out of proportion to those one expects from a simple empyema and suggest some additional grave condition; and should he die, as he may early in the disease, necropsy will often reveal a bilateral lobular pneumonia, pericarditis or some equally serious lesion. It is not implied that there is always this striking dissimilarity in the two groups of cases. The postpneumonic empyemas may present the grave symptoms of the postinfluenzal empyemas and at necropsy may show quite similar lesions; again, the postinfluenzal empyemas may present quite as mild symptoms as the postpneumonic empyemas. The question, then, often arises in both groups, whether the severity of the symptoms is due to the empyema alone or to additional complications the result of the respiratory infections.

Bronchiectasis.—In summarizing their discussion on lobectomy for bronchiectasis, Ballon and his associates state that, although improvements in methods of operating have been introduced in recent years, the operation remains even in the best hands one of the most serious procedures in the surgical repertory. From a list of collected operations performed by different operators and by different methods it is hardly fair to draw precise conclusions concerning the operative mortality and the probable chance of a satisfactory result. Yet the fact remains that in 212 collected cases no less than 72 patients (34 per cent) died apparently because of the operation and apparently in only 99 (47 per cent) was a thoroughly satisfactory result obtained. Even if one takes only the more recent and the more favorable figures, one still finds that a patient with bronchiectasis who submits to a lobectomy runs about a 15 to 20 per cent risk of dying because of the operation, and that if he recovers from the operation he has only about a 65 per cent chance of having a thoroughly satisfactory result with solid healing of the wound. In presenting this aspect of the results of lobectomy, the authors point out that there is no intention to be destructive or to argue that the operation is too dangerous or too uncertain in its results to be justifiable. On the contrary, much satisfaction should be gained from the fact that so many patients have been made well; for probably most of those who have obtained satisfactory results have been saved from death due to the natural consequences of the disease, and most of those who have died as a result of the operation would have died if left untreated.

Treatment of Dementia Paralytica with Inoculation Malaria.—Goodwin points out that secondary anemia sometimes follows inoculation malaria, and it is essential that complete blood counts be made twice weekly and oftener if deemed necessary. Dementia paralytica is more frequent in white persons but runs a more rapid course in Negroes. Life expectancy is increased by malarial therapy of dementia paralytica patients regardless of whether there is a complete remission in their condition. Quinine is definitely contraindicated when the red blood cell count is below 2,000,000 and the hemoglobin below 40. Patients with temperatures around 105 F. show the greatest amount of improvement. The results of inoculation malaria depend on the amount of parenchymatous degeneration present.

Low Back Pain.—According to Wheeler, one of the most difficult problems that confront the medical examiner in his endeavor to evaluate orthopedic disabilities is that of "lumbar spine" or low back pain. This pain may be due to a host of different causes, and it should be the aim of the examiner to determine the exact cause and govern himself accordingly. However, this is not an easy matter. In some instances the diagnosis is simple, but the exact classification of the symptoms many times constitutes quite a problem Especially is this true in cases of an industrial nature or when rehabilitation is sought and disability compensation enters into the problem The fact that lumbar pain presents a certain difficulty to the examiner is often known by the patient, and consequently it is most difficult to trip up a malingerer who presents himself complaining of pain in the lower portion of the back.

Treatment of Calculi of Urinary Tract.—In an analysis of the cases of ureteral and renal calculi at the Massachusetts General Hospital over a ten-year period, Peirson found that the results obtained in the treatment of these cases are not so good as should be expected Further analysis of these cases shows that the greatest cause of failure is due to delay in performing the operation It seems desirable that the public and the medical profession realize more clearly the seriousness of urinary calculi The author believes that every patient who is suspected of having a urinary calculus should have both a complete urinalysis and roentgen examination If a stone is discovered, cystoscopy should be performed and the patient carefully followed until the stone has been removed If attempts are made to remove the stone by nonoperative measures the case must be carefully followed from every angle and operation performed on the first appearance of signs of infection or increasing kidney damage Expectant treatment can be safely carried out only after a complete urologic examination and in cases in which the patient will be continually under rigid medical observation

The Anemias of Adolescence.—According to Fehland, the problem of the anemias of adolescence is closely interwoven with that of the spleen The clinical phenomena may not always readily reveal this relationship, but in a great many instances it is the pathologic spleen which serves as the underlying cause of a severe anemia Since the spleen is a part of the reticulo-endothelial system to which also belong the other lymphoid tissues of the body, it follows that the spleen reaches the height of its activity during adolescence and therefore also appears to be more subject to pathologic processes during this period The most common disease process is that which functionally produces a work hypertrophy and is usually associated with anatomic hypertrophy as well The result of such changes is commonly an increase in the normal physiologic function or destroying formed blood elements, whether these are red blood cells, as in hemolytic icterus, in which these cells are abnormally fragile, or white blood cells, as in early Banti's disease and Gaucher's disease, or even platelets, as in purpura hemorrhagica At other times the pathologic spleen resumes certain fetal characteristics in the production of embryonic white blood cells, bringing about the clinical syndrome known as myelogenous leukemia In all these conditions there obtains a fundamentally malfunctioning spleen, and the ultimate clinical phenomenon is that of an anemia Splenectomy, when indicated and when preceded by proper preoperative care, offers the best results with low surgical mortality

Physiology of Superficial Blood Vessels in Psoriasis. W. G. C. Paterson.—p. 310.

New Phase in Early Syphilis.—Drake and Thomson call attention to the fact that during the past decade many "arsenic-resistant" cases of syphilis have been described. These comprise individuals with resistant Wassermann reactions, patients in whom the original primary and secondary lesions have been highly persistent, and cases in which a partial involution of the early eruption has preceded an exacerbation of the same rash while the patients were still under treatment. But few have shown the strikingly rapid progression illustrated by a series of ten selected cases reported by the authors. On the whole, opinion seems to favor an obscure lack of response on the part of the individual. The fault cannot lie with the arsenic or any particular preparation of it because the majority of cases of early syphilis still progress satisfactorily to a cure, and unfavorable results have been reported with different preparations. The evidence as a whole points to the possibility that a more resistant strain of spirochete is beginning to make its appearance.

British Journal of Ophthalmology, London

16: 321-384 (June) 1932

*Clinical Significance of Ocular Musculature, with Especial Reference to Intra-Ocular Pressure and Circulation of Intra-Ocular Fluid. W. S. Duke-Elder and P. M. Duke-Elder.—p. 321.

William Briggs, M.D. (1650-1704). R. R. James.—p. 360.

Clinical Significance of Ocular Musculature.—The Duke-Elders point out that the diurnal pressure curve in the normal eye is a well known physiologic phenomenon. The pressure varies throughout the day by some 2 to 3 mm. of mercury; it is highest in the early morning before the patient commences the day's activities; after he gets up it falls, at first rapidly and then more slowly, until the evening when he retires to rest. Through the night in bed the reverse occurs: a rise occurs, again in two stages—a slow and gradual rise during the first few hours, and then a more rapid rise in the early morning. This is almost certainly due to the influence of the pressure-circulation: the absence of muscular activity during the night allows the pressure to rise, and the commencement of movements in the morning immediately lowers it. It is significant that in most cases of chronic glaucoma the diurnal variation is greatly exaggerated; and in case of doubtfully raised tension it is a wise procedure to take the tension of the eye while the patient is still in bed and before the activities of the day are commenced. The authors also call attention to the fact that the marked influence of the extra-ocular muscles on the intra-ocular pressure demonstrates the necessity for adequate akinesia in all intra-ocular operations. When it is remembered that a relatively mild contraction of the orbicularis raises the intra-ocular pressure from 27 to 53 mm. of mercury, the danger of loss of vitreous in a cataract extraction is obvious unless this muscle is thrown out of action. It follows that in all such operations the orbicularis should be paralyzed, either by injection of the facial nerve as it crosses the ramus of the mandible or by a local injection around the orbit; the former method is the one of greater precision, the latter the one of greater ease and certainty. Further, the action of looking down raises the pressure of the eye by the contraction of the recti, a rise which becomes quite marked if the action is forced. If every precaution is to be taken, a retrobulbar injection of procaine hydrochloride should be employed. This should be employed as a very dilute (0.25 or 0.5 per cent) solution injected immediately before one commences the operation, so that the muscles are not wholly paralyzed but merely weakened.

Ureterocele. J. Carver.—p. 132.
System for Permanent Filing of Cases of Genito-Urinary Diseases According to Diagnosis. H. P. Winsbury-White.—p. 139.

Transurethral Prostatic Resection.—Bumpus states that for transurethral prostatic resection the most satisfactory enlargement is that due to benign adenomatous hypertrophy of the gland. Healing is usually rapid even in cases in which considerable tissue is removed. The amount of tissue removed to relieve the obstruction will, of course, be greatest in this group. The next most satisfactory cases are the adenocarcinomas. After removal of obstructing tissue, recurrence is not so rapid as one might expect. The author has a specimen of a bladder removed at necropsy several years after resection in which the urethra was still free of obstruction, although the patient died with extensive metastasis to the viscera as well as to the skeleton. The mucous membrane was intact over the excised area in the specimen. The patient remained free of residual urine to the time of his death and was saved many years of catheter life by the procedure. Of course, the majority of patients die as a result of the disease before there is time for recurrence of the obstruction, but the resection was repeated in one case five years after the initial operation with relief of symptoms. The pathologist reported that the tissue from both operations was highly malignant. When the obstruction is due to prostatitis and only inflammatory tissue is excised at the time of resection, the results are prone to be disappointing. Such patients should not be subjected to resection until every effort has been exhausted to correct the prostatitis by other methods. When such methods have failed and residual urine persists, resection of the obstructing portion of the gland is justified. If the precaution of previous treatment by massage and irrigation is not followed, a stormy reaction may occur following operation, as to resect prostatic tissue in the presence of active infection is needlessly to court disaster. In such cases the author insists on local treatment until the prostatic infection appears as quiescent as can be hoped for. He also places the patient on a ketogenic diet, which renders the urine highly bactericidal in the majority of cases. If these precautions are taken, resection can be performed and may frequently break up the vicious cycle of prostatitis producing residual urine and the residual urine acting as an irritant to the prostatitis.

Comparison of Ergotoxine and Ergotamine.—Moir describes a method by which the response of the human puerperal uterus to oxytocic drugs may be directly recorded. By the use of this method in a series of puerperal patients he demonstrated that both ergotoxine and ergotamine bring about strong contractions in the puerperal uterus when they are administered by injection. Ergotoxine and ergotamine are indistinguishable from each other in their action on the puerperal uterus. The effect comes on slowly and takes from fifteen to forty-five minutes to appear after intramuscular injection. The most suitable dose for intramuscular injection is 0.5 mg. Oral administration gives slow and erratic results, even after comparatively large doses of the drug.

Menace of Obesity.—According to Bulmer, overweight after the age of 35 years increases the general mortality. The cause of obesity is usually increased carbohydrate diet. Treatment is simple and dietetic. Obesity and hyperpiesia are associated. Diabetes is probably a penalty of obesity in the majority of cases. Degenerative disease of a fatal nature in the heart, arteries, kidneys and liver are two and a fourth times commoner in the obese than in persons of standard weight, and three and three-fifths times commoner than in those underweight. Chronic cholecystitis and gallstones are much more frequent in the obese.

End-Results of Operations for Cholecystitis.—From a study of the symptomatic and end-results of operations in 153 cases of cholecystitis, Ross concludes that complete cure may be expected in 82.4 per cent. Of the rest, 10.5 per cent are relieved, while 7.01 per cent remain in statu quo. The symptoms of flatulent dyspepsia, including qualitative anorexia, completely disappear in more than 80 per cent of cases. It would appear that the absence of stones renders the prospect of cure perceptibly less. However, in cases of acute cholecystitis the absence of stones has no effect whatever on the prospect of cure. The operative mortality varies between 2 and 6 per cent, depending to a large extent on the type of case dealt with. In the author's series, dealing with every type of case, the mortality was 5.8 per cent. The average period of convalescence before full work is resumed is thirteen weeks.

Classification of Dysentery Bacilli.—Castellani states that, from the standpoint of the practical clinical bacteriologist, dysentery bacilli sensu lato may be conveniently separated, as suggested by him, as follows: 1. Dysentery bacilli sensu stricto (Bacillus dysenteriae Shiga-Kruse) do not clot milk, do not acidify mannitol. 2. Paradysentery bacilli (Bacillus paradysenteriae variety Flexneri; variety Hissi-Russelli) do not acidify lactose, do not clot milk, acidify mannitol. 3. Metadysentery bacilli acidify lactose, usually clot milk. A somewhat similar nomenclature may be used to indicate the various types of bacterial dysenteries: (1) bacterial dysentery, sensu stricto, due to Bacillus dysenteriae Shiga-Kruse (Eberthus dysenteriae Shiga-Kruse); (2) paradysentery, due to the different varieties of Bacillus paradysenteriae Collins (Eberthus paradysenteriae Collins, with its varieties Flexneri, Hissi-Russelli) and (3) metadysentery, due to the metadysentery bacilli (bacilli of the genus Castellanus Cerruti). From the point of view of the systemist the first two groups of bacteria (dysentery and paradysentery) belong to the genus Eberthus, subgenus Shigella, the third group to Cerruti's genus Castellanus.

*Focal Sepsis as Cause of Nephritis. A. C. Alport.—p. 1247.
*Menopausal Age and Mammary Carcinoma. E. K. Dawson.—p. 1251.

Use of Obstetric Forceps.—According to Crawford, the rules for the application of forceps are four. 1. Forceps may be applied only during the second stage of labor—that is, when the cervix is fully dilated and taken up. In rare instances, in which every other condition is favorable and delivery urgent, it may be permissible to incise a thin margin of cervix, but it is never justifiable to drag a fetus through a partially dilated os; the resulting lacerations may cause the mother's death or turn her into a chronic invalid. 2. The second rule is that the head must be fixed and the largest presenting diameter must have passed through the pelvic brim. Forceps, ideally, constitute an instrument for lifting the fetal head over the perineum. They may be applied on occasion to the head in the middle strait that is fixed, the largest diameter through the brim but not yet descended to the perineum. The application of forceps is a success only when their use leaves the mother no worse off than she was before their application, and when the child is born alive. If the maternal efforts fail to mold the fetal head through the pelvic brim, the dragging through of that head by means of forceps is as certain to kill the child as a craniotomy and is far more liable to injure the mother. Choice must rest between correction of malpresentation, cesarean section or craniotomy or, perhaps, pubiotomy. 3. The presentation must be favorable, vertex with the occiput anterior. Occasionally the use of forceps is permissible in face presentation in which the chin is to the front; in brow, when the whole head has passed into a roomy pelvis; or, rarely, in a vertex presentation with the occiput posterior. 4. The membranes must have been ruptured.

Present Position of Transurethral Prostatectomy.—Cabot states that transurethral prostatectomy is most obviously suited to patients with small glandular hypertrophies and in general to the smaller types of obstruction. He is still doubtful whether the operation can be satisfactorily applied to patients with great enlargement of the commissural subcervical glandular structures, in general the group commonly referred to as median lobe enlargement. Some of these enlargements reach great size and project backward, entirely covering the trigon and in some cases are more or less pedunculated. For this group he has hesitated to advise transurethral prostatectomy, though he is aware that it has been successfully employed in such cases. For the present at least he would prefer for these patients the suprapubic method of attack. He is also hesitant in regard to patients with large lateral lobes which have herniated backward through the vesical sphincter and come to lie in an obstructing position in the median line. The transurethral approach seems to him considerably handicapped in dealing with this group. Here suprapubic prostatectomy is at its best and he thinks further experience, at least, is required before admitting that the lesser procedure will produce wholly satisfactory results. For the moderate enlargements such as would be classified as one and two on a scale of four, the transurethral attack is well suited and has demonstrated satisfactory results. At the present time at the Mayo Clinic something like half of the cases of prostatic obstruction appear wholly suited to this method, and the proportion that is regarded as suitable has steadily increased during the last two years.

Focal Sepsis as Cause of Nephritis.—Alport shows that in the vast majority of cases of nephritis of various types it is possible to demonstrate well marked infection of the tonsils, antrums, teeth, and so on; this is particularly the case in subacute nephritis with much edema, and it is in these patients too that early removal of focal sepsis appears to give the best results. If the kidneys are badly damaged by the long continued excretion of a more or less virulent toxin, a surgical operation, by removing the source of the latter, may tend to slow down the progress of the disease; but the best results are obtained when the tonsillar or other infection has been searched for and eradicated at an early stage. In the chronic cases of nephritis with high blood pressure (200 mm. of mercury or more) even if infection is discovered, it is questionable whether the benefit obtained is sufficient to justify the risk of surgical intervention. The author suggests that specialist examination of the tonsils and antrums be undertaken at the earliest moment in all cases of pregnancy in which albumin in the urine or other signs of nephritis appear; also in postscarlatina, diphtheria, and other conditions in which residual tonsillar or associated infections tend to occur. Moreover, if focal sepsis is discovered it should be removed at once, as a precaution against the possibility of subacute or chronic nephritis later.

Menopausal Age and Mammary Carcinoma.—Dawson makes a survey of the duration of the menopause and sets up in parallel the frequency distributions of the menopause and the age incidence of cancer of the breast. He concludes from his figures that: 1. The age distribution of the menopause, as shown in his series of cases, has a longer range (from 30 to 59 years) and frequency than is commonly allowed. 2.

The figures representing the age distributions of the menopause and the incidence of cancer of the breast are not inconsistent with the hypothesis, suggested also by other considerations, that a correlation exists.

Tetanus Caused by Toy Pistol Wounds. Gwendoline Smith.—p. 1301.
Streptococcal Septicemia Complicating Epidemic Influenza. R. E. Smith.—p. 1303.

Reactions of Eye to General Disease.—Williamson-Noble points out that it is not probably realized what an intimate relationship measles has to the onset of convergent squint in children. The number of cases of squint which date from an attack of measles is large, and the reason for it is probably as follows: Nonparalytic convergent squint unassociated with disease of the retina or optic nerve is due in the ultimate analysis to failure of the fusion center to correlate the movements of the two eyes. Most of these cases occur in persons with hypermetropia and, if the hypermetropia is not corrected with glasses, clear vision can be obtained only by accommodation. The synergic action of convergence tends to occur at the same time and, if the fusion power is weak, little or no diplopia is caused and one eye becomes turned in. Binocular vision is a relatively late phylogenic acquisition and is therefore a function that is easily upset. An analogy with this is to be found in the action of anesthetics on the central nervous system, in which the highest centers are those to be first affected. The toxin of measles seems in a fair number of cases to have some peculiar selective action on the fusion center in the brain, and to bring about concomitant convergent squint, apart entirely from anything in the way of encephalitis. An uncommon sequel of measles is a degenerative change in the macular region of the retina which brings about marked diminution of visual acuity. Here again the phylogenic theory may come in, since macular vision is a relatively late acquisition. The author also points out that, although the Argyll Robertson pupil is in a high percentage of cases due to neurosyphilis, it is not necessarily pathognomonic of this disease. He mentions other diseases in which it occurs. Foremost is epidemic encephalitis, a disease that is particularly interesting, since some cases of it show the reversed Argyll Robertson phenomenon—i. e., reaction to light and none to accommodation convergence. Secondly, it has been found in cases of multiple sclerosis, and in syringomyelia and syringobulbia, while chronic alcoholism has been known to produce it. Most interesting of all, however, from the pathologic standpoint are the cases of cerebral tumor which are associated with an Argyll Robertson pupil. A sufficient number of cases would now seem to have been published to establish the truth of the observation that tumors in the region of the third ventricle, aqueduct or anterior corpora quadrigemina may give rise to this type of pupil reaction. In particular, injury of the anterior corpora quadrigemina appears to cause it.

Bacillus Coli Meningitis in the New-Born.—Gibbens reports that, in postmortem examinations on new-born infants during the last year or so at Queen Charlotte's Hospital, three cases of meningitis due to Bacillus coli have been seen. In only one of these was the diagnosis made during life; the other two were thought to be cases of intracranial hemorrhage. In one of the cases, Bacillus coli was recovered in pure culture from purulent cerebrospinal fluid during life; in the other two cases, examinations were made shortly after death, and not only did cultures yield the organism, but it was found in direct smears of the pus.

Serum Treatment of Experimental Streptococcal Infection.—Penfold and Butler tried two simple technics for the discovery of the antistreptococcal serum that might be expected to benefit individual patients infected with particular strains of streptococci. The technic consists, in one case, in the therapeutic use of various serums to protect mice against the experimental infection with the strain isolated from the patient and, in the second case, in the prophylactic use of serum for the same purpose. With both these methods it was found that, first, the infected mice may be unaffected by the exhibition of the serum; secondly, they may in a few cases be benefited by the serum; or, thirdly, they may be definitely injured by it. The treated animals may die much more quickly than the untreated. On the basis of their observations the authors conclude that commercial streptococcal serums are not infrequently dangerous when they are used to treat experimental streptococcal infections of mice. This dangerous effect may possibly be exerted in man. At present the authors feel it unwise to recommend streptococcal serum treatment in acute streptococcal infections in the human subject.

Blood Sugar in Arsphenamine Dermatitis.—Mu tested the sugar tolerance in nine cases of arsphenamine dermatitis. The dermatitis consisted of erythrodermia and papular, papulovesicular and purpuric exfoliative eruptions. The duration of the dermatitis varied from two to fourteen days. Eight patients showed delayed blood sugar curves and, in addition, four revealed a high fasting blood sugar content. One patient had diabetes. The blood sugar changes could be related to the extent and degree of the dermatitis but not to the type and duration of the eruption. The author suggests that the cause of the blood sugar changes is primarily associated with impairment of the glycogen metabolism of the liver brought about by a deleterious effect of arsphenamine on this organ. He recognizes, however, that the dermatitis itself may be a contributory factor.

Rupture of Uterus During Pregnancy.—Shen calls attention to the fact that spontaneous rupture of the uterus is one of the extremely rare complications of pregnancy. The most common cause of rupture before the onset of labor is probably that of a weak uterine scar following cesarean section. The other common cause is that of a direct injury to the abdominal wall. A case described by the author would seem to fall into this second group etiologically. Despite the fact that the patient herself was conscious of no severe discomfort at the time of receiving a blow in the abdomen, it seems that the blow must have been the cause of the rupture.

*Two New Clinical Signs of Auricular Tachycardia (Auricular Flutter). C. Laubry, D. Routier and A. van Bogaert.—p. 321.
Auriculoventricular *Dissociation by Double Command.* E. Gérandel.—p. 339.

New Clinical Signs of Auricular Tachycardia.—Laubry and his associates state that there are two clinical signs which permit diagnosis of auricular flutter. They are: (1) anisosphygmia, or inequality of the pulse, and (2) appearance of a third sound in diastole giving a rhythm of three sounds characterized by a continuous variability. The anisosphygmia is of two types: the periodic or alternating type and the aperiodic or irregular type. The alternating type is frequent in regular and rapid flutter. In irregular anisosphygmia the amplitude of all the pulsations is unequal. Irregular anisosphygmia, well known in complete arrhythmia, is also clearly perceived in slight irregularities which escape auscultation and guides the diagnosis toward auricular flutter. In certain regular flutters an alternating or variable oscillation of the pulse takes on the appearance of irregular anisosphygmia. The rhythm of three variable sounds is composed of two normal sounds, to which is added a third dull sound which gives a sensation of rising to the hand or ear applied at the level of the beating of the apex of the heart against the chest wall. The relation of the superadded sound to the two normal sounds is extremely variable. For the normal rhythm is substituted either a doubling of the first sound or a presystolic or protodiastolic gallop. In long diastoles a fourth dull sound is heard comparable to the one heard in block. This rhythm of three variable sounds is not a characteristic sign of flutter, yet it is of diagnostic value. Although it actually exists independently of auricular activity, the latter contributes in large measure to its production, and its variability is due to the anisochronism, even if slight, of the flutter. From the standpoint of prognosis, the rhythm of three sounds has the same significance as the usual gallop because it is the expression of an abnormal state of the ventricle which frequently results from a myocardial miopragia.

Case of Human Anthrax Cured by Serum Therapy. L. Bérard and R. Desjacques.—p. 456.

Rôle of Sympathicus in Pathogenesis of Edema.—Brandao reports the case of a woman, aged 25, with severe, painful edema of the left hand and forearm which developed without trauma, inflammation or poisonous bite of an animal and resisted all medical treatment. Periarterial sympathectomy resulted in complete disappearance of the edema in three days, but it reappeared and in eighteen days had attained the same degree as before the operation. Extirpation of the first and second thoracic sympathetic nerve ganglions resulted in rapid disappearance of the edema, but six months later there was another recurrence, this time limited to the hand. The edema receded immediately after extirpation of the remainder of the left cervical sympathetic nerve, including the superior ganglion, and the patient is still well three months after the operation. A similar case of Leriche is cited. The author, in agreement with the majority of investigators, believes that peripheral edema of unknown cause is due to a disturbance of the sympathetic nervous system; but he does not agree with them that the mechanism through which this is brought about is one of vasodilation or vasoconstriction. He thinks that the sympathetic nerve, besides its rôle of vasodilation, acts directly on the vascular endothelium by means of a vasosecretory action capable of making the fluid exchange oscillate. Like Leriche and Fontaine, he admits the existence of two edematogenic reflexes, one short and one long. The edema in his case and Leriche's was the result of morbid exaggeration of the long reflex, suppression of which by surgical intervention made the edema stop immediately. Morbid exaggeration of short reflexes is seen in edemas following phlebitis. In both cases, change of the integrity of the venous wall plays the principal part in the genesis of the disturbances appearing in the extremities. As far as the short reflex is concerned, he thinks there are peripheral centers which suffice to maintain the fluid exchange without any connection with the bulbomedullary centers. The disappearance of the edema after the cervicodorsal gangliosympathectomy in the cases reported demonstrates the possibility of maintaining normal regulation of the lacunar or lymph spaces by action of a mural apparatus left to itself, once the abnormal excitation transmitted to it by the seriously altered long reflex is suppressed. In conclusion, the author states that in his case resection of the entire sympathetic chain was probably unnecessary; division of the branches communicating with the brachial plexus would have sufficed for the treatment of the edema, but the former method was undertaken because it was easier and more certain of success.

General Anesthesia by Rectal Oleo-Etherization. A. Chalier.—p. 1069.
*Myelogenous Leukemia with Relative Polymorphonuclear Neutrophilic Leukocytosis. P. Emile-Weil and G. Sée.—p. 1071.

Myelogenous Leukemia with Relative Polymorphonuclear Neutrophilic Leukocytosis.—Émile-Weil and Sée state that there is a form of myelogenous leukemia with all the clinical characteristics of this disease but differing from the common form by the absence of a variegated leukocytosis and its replacement by a polymorphonuclear neutrophilic leukocytosis. The first of two cases reported concerns a woman with enormous splenomegaly operated on because the case was not diagnosed as leukemia. The spleen was typical of myelogenous leukemia and contained only mononuclear leukocytes, while in the blood with a leukocyte count of 35,000 to 40,000 there were 77 per cent polymorphonuclear leukocytes and only 5 per cent myelocytes; there was a strong normoblastic reaction. Following splenectomy the blood gradually assumed the character of a real leukocytosis and the patient died seven months after intervention. Recognition of this form of myelogenous leukemia is of practical importance to the clinician because of the grave danger incurred by surgical intervention and the extremely beneficial influence of roentgen therapy. This type of leukemia differs from primary splenomegaly in that it is more constantly accompanied by hepatic hypertrophy from the start, the sclerosed organs are firm but not hard, there are fewer functional symptoms, and there is a high polymorphonuclear leukocytosis with myeloid reaction never found in primary splenomegaly in the absence of infection. The authors consider this form of leukemia a preliminary stage of ordinary leukemia. From the theoretical standpoint it shows the existence of a leukemia in which the blood does not reflect the cellular picture of the hematopoietic centers, and the myelocytes, granular or not, are capable of continuing their evolution to their adult form in the blood stream.

Revue Médicale de l'Est, Nancy

60: 425-492 (June 15) 1932

Valgus Flatfoot. M. Froelich.—p. 425.
Minimum Amputation in Lesions of Tarsus. A. Hamant and P. Chalnot.—p. 440.
*Deformation of Bones in Tetanus. Mutel.—p. 458.
*Hypertrophic Stenosis of Pylorus in Nursling. L. Grimault and E. Wilwertz.—p. 464.

Deformation of Bones in Tetanus.—Mutel reports a case of posttetanus sternal deformation characterized by abnormal convexity of the lower portion of the sternum with a lateral flattening of the anterior segment of the ribs resulting in an appearance of marked chicken breast. The patient had retained the attitude of orthotonus, instead of the more frequent opisthotonos, during the illness. The sternal deformation was the result of complex muscular actions; the chest muscles projected the sternum forward, the recti abdomini pulled the xyphoid process forward and the abdominal muscles flattened the ribs laterally. While all tetanus patients present muscular contraction, bony deformation is rare. The intensity of the muscular contraction and convulsive attacks of tetanus are capable of provoking deformities by attrition of the bony tissue, but only in the presence of a preexisting fragility of the bone tissue. Many explanations have been given by different authors for the origin of this fragility. As almost all the cases reported concern adolescent individuals, the author thinks the predisposing cause may be the malleability of the skeleton at that age, or the condition of bony dystrophy more or less discrete which is designated by the name of late rickets.

Hypertrophic Stenosis of Pylorus in Nursling.—On the basis of personal observations and a study of the literature, Grimault and Wilwertz state that when a nursling who has been previously well suddenly presents disturbances consisting in projectile vomiting, obstinate constipation with rare meconial stools, oliguria and rapid loss of weight without infectious phenomena, one should think of hypertrophic stenosis of the pylorus and make a roentgenologic examination to confirm the diagnosis. Medical treatment, consisting in more frequent and shorter nursing periods and the administration of antiemetics and antispasmodics, should be instituted; if it fails, pylorotomy should be performed immediately. This operation will be followed by *immediate and complete cure. The authors report* a case of hypertrophic stenosis of the pylorus in a nursling, aged 35 days, which presented all the diagnostic symptoms of this disease except that the pyloric tumor could not be palpated, which is not surprising, as the pylorus in nurslings is sometimes below the liver, even behind the stomach. Roentgenologic examination showed that none of the barium ingested had passed into the intestine in twenty-four hours, thereby confirming the diagnosis. On intervention, a pyloric tumor larger than an olive was found. Pylorotomy was followed by cessation of vomiting and a rapid gain in weight. The authors also report a case of pseudostenosis which resulted from pylorospasm without the existence of a pyloric tumor. The case responded to the dietetic and medical treatment outlined. The response to medical treatment differentiates pylorospasm from stenosis due to a pyloric tumor.

*Spontaneous Fragmentation of Urinary Calculi. A. Paladini.—p. 946.
Can Roentgenographic Investigation of Human Placenta Be Attained? A. Tommaselli.—p. 954.

Spontaneous Fragmentation of Urinary Calculi.—Paladini states that spontaneous fragmentation of urinary calculi rarely occurs. He cites a patient with thirteen entire calculi and 930 fragments. The fragments were generally pyramid-shaped or dome-shaped. Each calculus was divided into large or many small fragments. Chemical investigation revealed that 70 per cent of the entire mass consisted of uric acid without ammonium urate and free carbonic acid with little organic substance. The fragmentation in the author's case continued over a period of years; the bladder contraction of the patient did not in any way determine fragmentation, because the patient had chronic prostatitis with bladder distention and no symptoms of irritation of the bladder. He cites the following theory of Ord as the most satisfactory explanation: The disintegration is due to a liquid filtrating through the strata of the calculus, arriving at the nucleus and causing the swelling of the organic skeleton of the calculus, which in turn causes disruption.

*Serum Coagulation of Weltmann in Pulmonary Tuberculosis in Comparison with Erythrocyte Sedimentation Speed. G. Nannini and B. Davolio Marani.—p. 515.

Sites of Predilection of Pleural Adhesions.—Tarantola states that pleural adhesions occur more frequently on the upper and smaller lobe of the lung and especially at the apex or the posterolateral surface up to the interlobar space. Occasionally the site of the adhesions is at the base of the upper lobe. The lower lobe is rarely a site of adhesions but its superoposterior, upper and diaphragmatic surfaces are sometimes predisposed to them. Adhesions seldom occur on the median lobe. They are frequently found between the leaves of the interlobar pleura. The sites of adhesions are found as a rule on those parts of the lungs presenting tuberculous lesions. The author states that adhesions are often spread by the action of the pneumothorax but that they do not act harmfully on the underlying parenchyma.

Serum Coagulation of Weltmann in Pulmonary Tuberculosis.—Nannini and Davolio Marani present the results of a study of Weltmann's serum coagulation on forty-nine patients with fibrous, mixed and exudative tuberculosis. They use the following technic: To an equal amount of serum (0.1 cc.) they add 5 cc. of a solution of calcium chloride diluted in arithmetical progression from 0.1 per hundred to 0.1 per thousand; *for this they prepare ten solutions which contain for 100 cc. of* distilled water 1 cc. of calcium chloride at 10 per cent, and then 0.9 cc., 0.8 cc. and so on until they arrive at 0.1 cc., which gives the greatest dilution and corresponds to 0.1 per thousand. They then add 0.1 cc. of serum to 5 cc. each of these solutions of calcium chloride and boil the whole lot in a water bath for fifteen minutes, during which time the tubes must be shaken continually. The authors state that the reaction of Weltmann demonstrates a displacement to the right in productive and nonactive processes and a displacement to the left in exudative progressive forms. In a combination of exudative and fibrous processes, the Weltmann reaction can give the result only of a present and prevalent process. A normal result can be obtained in cases of tuberculosis tending toward cirrhosis and of stationary and cavitary tuberculosis if the flare up from the cavern is practically over. The erythrocyte sedimentation speed is always accelerated in pulmonary tuberculosis. The lower values are in serious destructive forms, the higher in forms tending toward sclerosis. Serum coagulation reveals best the fundamental anatomopathologic state of the disease form, while the reaction of sedimentation is the exponent of humoral conditions of the organism at the expense of a greater or lesser bacillary intoxication. The two reactions are almost identical in their dependence on an equilibrium disturbance of protein fractions (increase of globulin, diminution of serum albumin). By removing a certain amount of fibrinogen in the process of coagulation and by precipitating some of the globulin with calcium chloride, one finds the serum albumins in so weak a proportion as to necessitate for coagulation a greater amount of calcium salt (increase of electrolytic threshold). The internal mechanism of serum coagulation in fibrous formation appears more obscure when it happens in the lower dilutions beyond the limit of normal subjects. In conclusion the authors state that the sedimentation speed can serve to correct or complete the results of the reaction of Weltmann but that in most cases the latter is of greater value for the diagnosis of the form of the disease.

*Hyperstereoroentgenography in Differential Diagnosis of Round Intrathoracic Shadows. F. R. Partearroyo, J. Miñana and F. Blanco.—p. 509.
Hepatosplenography Following Injection of a Thorium Dioxide Preparation. M. F. Arce.—p. 515.

Hyperstereoroentgenography in Diagnosis of Round Intrathoracic Shadows.—Partearroyo and his associates state that, during the performance of a roentgen examination of the chest, both the pathologic formations and the vessels intercept the roentgen rays and produce a shadow in the roentgenogram. If one or several vessels are orientated in the same direction as that of the roentgen rays, they project themselves as round shadows in the roentgenogram. In clinical practice, vascular shadows have been interpreted, sometimes, as caused by tuberculous nodules. The differentiation between vascular and *nodular shadows may be made by* the characteristics in the roentgenogram: general localization, number of images, seat, form and homogeneousness of the shadow However, the indispensable condition to consider a shadow as given by a tuberculous nodule (and hence as having a pathologic meaning) is its stability, that is, that its dark color has always the same intensity in serial roentgenograms. The authors emphasize that they do not mean that all pulmonary shadows of various sizes are always vascular projections, although they call attention to the fact that not all the round shadows observed in the hilus and parahilus are given by tuberculous nodules; that is, that the shadows of small assumed tuberculous nodules in the peripheral area of the lung are not always of a hematogenic origin. Frequently the vessels project like shadows that are similar to those given by nodules of a hematogenic origin Hyperstereoroentgenography is the most perfect method to differentiate these types of shadows in the roentgenogram of the chest

Acute Calcareous Bursitis of Shoulder.—Erb and Friedriszik point out that since Duplay described periarthritis humeroscapularis there has been a tendency to resort to this diagnosis in many of the disorders in the region of the shoulder joint. The description of four typical cases of acute calcareous bursitis shows that the pain in the shoulder frequently develops without preceding trauma or after a slight one The nocturnal exacerbation of the pain is especially characteristic, and the patients are unable to use the arm. Abduction is impossible on account of the severe pain The point particularly sensitive to pressure is localized by most patients on the tuberculum majus or directly below the acromion Roentgenoscopy corroborates the diagnosis of calcareous bursitis by revealing a shadow about the size of a bean either caplike above the tuberculum or in the space between tuberculum and acromion. Treatment with hot air or, better yet, with diathermy quickly counteracts the pain and restores the function of the arm within several weeks. Roentgenoscopy reveals that the calcium depot soon begins to disappear, and later examinations show complete disappearance. The authors point out that there are also cases in which calcium depots are located in the subdeltoid space, particularly on the tendon of the supraspinatus, but these depots have, at least in the beginning, no connection with the bursae If after treatment with heat or with diathermy the acute pain and also the calcium depot disappear, the disorder was acute calcareous bursitis; but if this is not the case tophaceous gout may be assumed, for which, in case of failure of conservative therapy, operative removal of the calcium focus is advisable

Artificial Hardening of Anterior Mediastinum.—According to Polano, the main cause of the occasional failures in the surgery of the sternum is, besides the circulatory weakness, the mediastinal flutter. The unphysiologic mobility of the mediastinum causes severe circulatory and respiratory disturbances, for a normal circulation is dependent on the immobility of the mediastinum, as it exists before the thorax is opened. To preserve this immobility after the equilibrium has been disturbed two methods are possible; namely, the use of Sauerbruch's cabinet and artificial hardening of the mediastinum. The latter method, which Rehn first demonstrated in animal experiments, becomes understandable when the anatomic conditions are considered, *which the author investigated carefully on* human cadavers. He explains the significance of the anterior mediastinal cavity for the circulation, particularly the superior vena cava The various anatomic relations of the pericardium to the manubrium and corpus sterni lessen the rigidity of this upper portion of the mediastinum, but by a technic of injection it is possible to make the mediastinum firm The fact that this can be done in human subjects provides a valuable aid in preventing serious pressure disturbances in interventions on the thorax, and thus the artificial hardening represents a helpful addition to the Sauerbruch cabinet

Contrast Examination of Spleen and Liver with Thorium Dioxide.—Buchner reports observations which indicate that a considerable quantity of the thorium dioxide preparation that is introduced for visualization of the spleen and liver cannot be eliminated from the organism The retention produces functional weakening of the reticulo-endothelial system and of the lymph follicles of the spleen Whether serious late complications will result from the blockage will require further investigations

Reduced Resistance of Erythrocytes in Intestinal Disorders.—It is pointed out by Schwarz and Taubenhaus that a change in the resistance of the erythrocytes, particularly a reduction of the resistance toward sodium chloride solutions, is generally considered characteristic for hemolytic icterus However, so far the literature has no reports on a decreased resistance of erythrocytes in gastro-intestinal disorders. For this reason the authors feel justified in reporting the clinical histories of two patients with severe gastro-intestinal disturbances, in whom there existed hypochromic anemia, hypocholesteremia and a considerable reduction in the resistance of the erythrocytes toward physiologic solution of sodium chloride Both patients had a tumor of the spleen, but there were no signs whatever for hemolytic icterus The causes of the decreased resistance of the erythrocytes was not demonstrable, either clinically or experimentally. But the authors think that the reduced cholesterol content may be of significance, since several investigators have called attention to the relation between the cholesterol content of the blood and the resistance of the erythrocytes.

Disturbances of Acid-Base Equilibrium and Edema.—In summing up his observations, Fliederbaum writes as follows: 1. Patients with edema have a tendency to retain acids and bases in their tissues; the retention of acids is primary, that of alkalis, resulting from their attraction by the excess of acids, is secondary (neutralization retention). 2. The local acidosis of the skin and of the subcutaneous connective tissue increases the affinity for water; the local alkalosis decreases it. 3. In patients with edema, acids increase the retention of water and alkalis decrease it.

Oral Sugar Therapy in Icterus Gravis.—Thinking that it would be a distinct gain to be able to counteract severe disorders of the liver not only by the combined administration of dextrose and insulin but also by oral administration of sugar alone, Scholl and Steiner studied the efficacy of sugar without insulin in diseases of the liver that resemble acute yellow atrophy. They were induced to try this by the observation that rats which were given large amounts of carbohydrates were less susceptible to phosphorus The authors decided to employ sugar therapy in patients who after prolonged arsphenamine medication had developed a disturbance which can be designated as subacute yellow atrophy of the liver. The patients received a diet of various farinaceous foods, and in addition they were given daily from 30 to 60 Gm of levulose The six patients who were treated in this manner either showed considerable improvement or were completely cured

Carbon Dioxide in Respiratory Disturbances of the New-Born.—After mentioning the measures that are usually employed to counteract the respiratory disturbances of the new-born, Peiper and Cammann call attention to the use of carbon dioxide mixtures, as recommended by Yandell Henderson. In order to determine the influence of carbon dioxide on the respiration of the new-born, the authors studied its action on premature infants because the latter are especially subject to respiratory disorders The respiratory changes that took place under the influence of carbon dioxide mixtures were graphically recorded It was found that the changes were not regular. In a number of cases shock reactions were noted in the beginning of the administration, and there were also permanent reactions. Occasionally, interruptions of the respiration were observed. In infants in whom there was a gasping for breath, carbon dioxide was less effective than other measures, such as artificial respiration and the administration of a lobelia preparation or of epinephrine. Thus the authors are not convinced that the respiratory disturbances in nurslings can be effectively treated with carbon dioxide.

Differential Diagnosis of Thrombosis of Splenic Vein.—On the basis of three case reports, Schmiedeberg shows that (1) even if most or all of the clinical manifestations of thrombosis of the splenic vein are present, this is not an absolute proof that it really exists, and (2) whenever these symptoms do exist, no matter whether they are or are not caused by a thrombosis of the splenic vein, the removal of the enlarged spleen gives the best prospects for improvement or cure

Contagiousness of Icterus Catarrhalis Before Manifestation of Symptoms.—Seyffarth states that although the length of the incubation period in icterus catarrhalis has been repeatedly discussed, nothing has so far been said as to whether the infecting person transmits the disease during the incubation period, the prodromal period or after the symptoms have become manifest. For this reason the author feels justified in reporting the clinical history of a child who was infected with icterus catarrhalis by a person in whom the prodromal stage began twelve days later and the icterus became manifest eighteen days later. In the child the prodromal stage began twenty-three days following the contact with the infecting person, and the icterus became manifest on the twenty-sixth day

Backache, with Especial Consideration of Sacralization.—Philipp points out that when gynecologic disorders are absent it is usually difficult to detect the cause of backache in women Therefore, if a careful gynecologic and general examination does not reveal the cause, he advices roentgenologic examination He himself did this in a large number of cases and in order to be better able to evaluate the roentgenograms he compared them with photographs of pelves from an obstetric collection In discussing sacralization and lumbarization he states that he observed all the successive stages, beginning with simple anomalies of the transverse process and ending with bilateral sacralization of the fifth lumbar vertebra, in which there exist five instead of four pairs of sacral foramina. Observations on a number of women convinced him that those patients complain of backache in whom the vertebral statics are disturbed, in whom demonstrable articular changes exist, or in whom these two conditions concur. However, in patients with coalescence of the vertebrae but without disturbed statics or without articular changes, backache may be absent In discussing the prognosis the author states that whenever the pain concurring with sacralization is caused by static disturbances, adaptation and with it disappearance of painfulness can be expected after a shorter or longer period Articular pains may persist for a number of years, but after that they likewise disappear In the last part of the article the author emphasizes once more the great value of roentgenoscopy.

Bacterial Flora of Uterus During First Week of Puerperium.—In reviewing the literature on the bacterial contents of the uterine cavity during the puerperium, Petrowa found that the majority of the earlier studies were made with the aerobic methods of cultivation, whereas the micro-organisms of the vulva and of the vagina are primarily anaerobic. She thinks that this explains the contradictory results of some of the earlier investigators, and in the course of her studies on forty healthy puerperas, each of whom was subjected to two tests, she employed the newest methods for the cultivation of anaerobic organisms. In 10 per cent of the cases, both tests were negative, and in 35 per cent one test was negative

Micro-organisms enter the uterus most frequently in the first twenty-four hours of the puerperium, but in some instances they enter on the third, fourth or fifth day. In some instances the types of micro-organisms change, or several are present at the same time. Such variations are probably due to bactericidal powers of the uterus, to discharge of the fluid and to the antagonism of the micro-organisms to each other. The invasion of the uterus by pathogenic organisms does not necessarily cause clinical changes in the course of the puerperium.

So-Called Hepatolienal Disorders in Children.—Studies on 127 cases convinced Massloff that, in the development of the hepatolienal syndrome, the endogenic factors, a congenital weakness and a constitutional predisposition play an important part. The different forms of hepatolienal disorders have in common the involvement of the connective tissue apparatus, and observations indicate that the changes in the connective tissue are not secondary but rather primary. The designation of hepatolienal disorders is therefore not entirely correct, since liver and spleen are important only so far as the pathologic processes of the connective tissue become manifest especially in them. Essentially these disorders are not diseases of the liver and spleen but rather of the connective tissue or, more correctly, of the entire mesenchyme, for which reason the author designates them as mesenchymoses. He differentiates various forms of mesenchymoses, and in discussing the practical results of his studies he points out that in the combat of the hepatosplenic disorders the entire organism should be considered and the object should be general strengthening of the organism, the reduction of the predisposition and the elimination of injurious factors from the milieu. Children who deserve especial care and observation are those with hereditary deficiencies (alcoholism, mental disturbances, general debility of the parents and syphilis), as well as children from large families with a high mortality rate. Endangered are also children with backward physical development, with dry skin and with decreased turgor. Another group of children deserving especial consideration are those with the various diseases of the blood (splenic anemia, thrombopenia), with chronic constipation, with diarrheas, with enlarged liver and spleen and with general debility, also children who have passed through the so-called icterus simplex. For such children hydrotherapeutic measures, gymnastics, massage and light sports are advisable. Infections should be guarded against, and alcohol and large quantities of meat should be avoided.

Bilateral Pneumothorax Treatment in Pulmonary Tuberculosis. S. von Záborszky.—p. 49.
Expectorant Treatment of Disorders of Respiratory Organs. F. Köhler.—p. 55.

Roentgen Symptomatology of Intestinal Tuberculosis.—Rother states that the general clinical observation does not permit a definite decision about the tuberculous involvement of the intestine, for postmortem examinations have revealed that tuberculous patients who during life had had severe intestinal symptoms were free from tuberculous lesions, whereas others who had had slight symptoms showed severe lesions. Even the presence of tubercle bacilli in the feces is not demonstrative for intestinal tuberculosis, since in open tuberculosis there is the possibility of swallowing sputum containing bacilli. Intestinal roentgenoscopy of 150 tuberculous patients convinced the author that in the majority of cases the presence, type and location of tuberculous lesions of the intestine are revealed by this method. In discussing the technic of intestinal roentgenoscopy, he evaluates the two methods of introduction of the contrast medium: the contrast clysma and the contrast meal. He recommends beginning with the contrast clysma, because it is quicker and usually gives a good roentgenogram of the large intestine. While the medium is being introduced, the outline, haustrum formation and motility of the large intestine are carefully observed before the roentgen screen, and the sensitiveness to pressure is likewise watched. The author further describes the roentgenologic outlines of the various tuberculous lesions that are observed on the intestine: swelling or ulcerations of the mucous membrane, the aspects of the so-called polypous-dysenteric intestinal tuberculosis, further stenoses, prestenotic dilatations, and particularly the changes at the site where large and small intestine join. Although the introduction of the contrast medium by means of the clysma reveals the condition of the large intestine, it is nevertheless advisable to examine the small intestine; this is best done by means of oral administration of the contrast medium. After describing characteristic tuberculous changes the author gives several case reports and shows roentgenograms of certain lesions. He emphasizes the significance of roentgenoscopy particularly for surgical treatment.

Invagination Following Gastro-Enterostomy. A. Angerer.—p. 1572.

Method for Blood Transfusion.—In the introduction Boller enumerates the requirements of a good technic for blood transfusion; he thinks that none of the numerous methods fulfil all of them. He discusses particularly some of the disadvantages of the addition of sodium citrate to the blood and shows that although it does not, as some assert, injure the erythrocytes, it causes more severe fever reactions than unchanged blood; the fact that the blood comes in contact with the air is likewise a disadvantage. The author then describes his own method of blood transfusion, which he says can be employed by any physician who has a good technic of intravenous injection. In this method the blood is withdrawn with syringes from the vein of the donor and introduced directly into the vein of the patient. To make it possible to transfuse by means of thin cannulas larger quantities (500 cc. and more), a method had to be found to prevent clotting. This was done by inserting between the needle and the syringe a special device that makes it possible to rinse the cannula with physiologic solution of sodium chloride while the blood stream is interrupted during the change of syringes. The author gives a detailed description of the device, which is the same for the needle of the donor and of the recipient, and then describes the technic of the transfusion, which requires the presence of two physicians and of a nurse. A transfusion of 500 cc. can be completed in from five to eight minutes, but if the patient is extremely weak it can be given more slowly. The author employed this method in eighty cases and never observed injurious effects either on the donor or on the patient.

New Type of Bone Suture.—After discussing the indications for a bone suture, Petřivalský describes and illustrates his method. With an electric drill, oblique canals are made through the compact mass of the bone above and below the fracture. Through these canals a rust-free steel wire is passed, crossed in the figure-of-eight manner and then tightened with specially constructed forceps In evaluating the advantages of this wire suture, the author emphasizes not only that the crossed wire can be tightened readily but also that the parts of the bone are thereby approximated exactly. Where the wire touches the periosteum this is opened so that the wire is mostly subperiosteal, but otherwise the periosteum should be preserved as much as possible If the bone is narrow one wire suture is sufficient, but in the case of the humerus or of the femur or of the flat cranial bones at least two sutures are necessary. The figure-of-eight wire suture can be employed also in case of splintering of the bone Another advantage of this method is that the wire passes only through the compact portion of the bone and the marrow and the formation of a marrow callus is not disturbed The author has employed this method for about a year, and he is entirely satisfied with the results He does not claim that it is the best method but emphasizes its simplicity and states that the anatomic as well as the functional results are satisfactory

Diagnosis of Alcoholic Intoxication: Gans-Rodiet Symptom.—Ilyin states that his experimental studies with animals and his clinical observations substantiate his belief that hemianesthesia of the sclera, or the symptom of Gans-Rodiet, is present in various forms of clinical alcoholism and whenever alcoholic intoxication has an etiologic significance This symptom may be present together with symptoms indicating disturbance in the nictitating and supra-orbital reflexes, with anesthesia of a peripheral type, with ataxia in the hands and sluggishness of the facial expression The phenomenon is due to a disturbance in the motor reflexes of the mimetic muscles especially those innervated by the facial nerve and the first branch of the trifacial nerve

Psychic Disturbance in Chorea Minor of Adolescents.—Kogan gives four personal observations consisting of patients aged 16, 17, 18 and 23 with psychic symptoms in favor of a diagnosis of chorea minor The diversity of psychic symptoms in both schizophrenia and chorea minor may be explained by the contiguity of the regions in the brain responsible for each disease The author believes a virus may have been responsible in two of his cases, while the fact that there was an epidemic of rheumatism in the vicinity may explain the independent development of chorea minor in the other two patients as well as the simultaneous appearance of chorea minor in all four of the patients, who were older than those usually affected with chorea minor

Constitutional Predisposition to Chorea Minor.—Osipova states that the appearance of chorea minor is dependent not only on a toxico-infectious factor but also on an inherited predisposition to the disease Her studies proved that the various elements of the somatopsychic structure of the disease were similar to those present in the parents The somatic constitutional changes were characterized by general weakness, cardiovascular deficiency, and predisposition to various infections; the neuropsychic constitutional changes were characterized by instability of the sympathetic nervous system, weakness in the sensorimotor nervous system, and low psychic tonus Extensive catamnestic studies led the author to believe that constitutional predisposition to chorea is peculiar to asthenic types of individuals with a specific motorium and that chorea is a cerebral disease with changes in the motor as well as the sensory spheres.

Sprue Psychosis.—Viyasnovskiy discusses six cases and concludes that patients with sprue can develop psychoses at the onset as well as at the termination of the disease. Delirium and hallucinations predominate in the catamnesis and the psychic disturbance should be regarded seriously in the prognosis quoad vitam. The psychoses appear most often in individuals with a burdensome inheritance or with a constitutional weakness of the nervous system. In fatal issues, examination at necropsy shows pathologico-anatomic changes specific for sprue and also microscopic and macroscopic changes in the central nervous system The latter are of circulatory origin and are a result of instability of the hemato-encephalitic barrier.

Study of Sleep.—Mikheev presents the catamnesis in five patients with tumor of the brain and a tendency to sleepiness during the course of the disease. Sleepiness seemed to be concomitant with the appearance of ptosis and paralysis of the upper eyelids. The author's anatomopathologic studies led him to believe that the zones for regulation of sleep lie in the region of the optic thalamus and particularly the aqueduct of sylvius

Circulatory Relations in Varicose Syndrome.—Haxthausen says that measurement of the temperature of the skin in varicose lower extremities showed no noticeable decrease from the normal in the cutaneous blood supply. The hypothesis of stasis in varices as the cause of ulcer and eczema and the theory of nutrition of the skin with "used" venous blood cannot therefore be maintained Varices diminish the ability to counteract hydrostatic pressure by muscular movements and thus lead to the formation of filtration edemas and defective resorption of these. The patients and the regions where this condition is most marked are especially liable to cutaneous complications, and there is therefore reason to assume a causal relation between the two

Roentgen Diagnosis of Intestinal Invagination.—In Thomsen's first patient, a child aged 3, the roentgen picture supported the diagnosis of invagination Laparotomy revealed a ring of enlarged lymph nodes about the right flexure of the colon, to which the localized intestinal spasm during the roentgen examination is ascribed. The patient had enteritis with melena In the second, fatal case, in an infant aged 9 months, with rectal prolapse, the roentgen diagnosis was also misleading On operation an ileocecal invagination was found, complicated by fibrous bands encircling various portions of the intestine After disinvagination, three perforations were seen on the intussusceptum

ADVANCES IN ANESTHESIA FROM THE STANDPOINT OF THE SURGEON

FRANK H. LAHEY, M.D.
BOSTON

It has been my lot to grow up in surgery during the period of the greatest development of anesthesia and of anesthetists. It has been my good fortune to have associated with the clinic, from its beginning, a full-time anesthetist, and to see the department of anesthesia increased until we now have four full-time anesthetists: two physicians and two nurses. This, together with my own natural interest in anesthesia, has provided me with considerable experience, which has in turn permitted me to arrive (at least for my own benefit) at quite definite conclusions.

In my early days in surgery, anesthesia was in a far from satisfactory state. The anesthetic was given by the youngest and least experienced of the hospital interns, who in most instances had had little or no training or instruction in the technic of administration. Responsibility for the anesthesia was claimed or accepted by the operating surgeon, who often impatiently demanded rapid induction, and who dictated the depth to which the patient was to be carried.

The anesthetizing of private patients was done by young surgeons who had recently graduated from surgical house-officerships but who had no operations to do. Giving anesthesia for operating surgeons in private hospitals was accepted as a stepping-stone to higher things in surgery. It kept one in contact with influential surgeons (patronage is not limited to Washington!), and it providentially furnished the income necessary to existence.

So long as anesthesia was limited almost entirely to the administration of ether, this was not a really bad system, supplying, as it did, young men fresh from hospital services with good general training, and assuring them continuation of their association with operative procedures. Its drawback was that these men had no deep and permanent interest in anesthesia: It was to them but a hurdle over which the course led to surgery, an experience to be gotten through with and relegated to the background as soon as possible; and while those who did it wanted to give as good anesthesias as they could, so that they would be asked again and so earn a living, they did not want to be known as too good in anesthesia, lest they become known as anesthetists, and thus be sidetracked from their main object in life—that of surgery.

Having personally progressed through the vicissitudes of anesthesia as just described, I became at times acutely aware of the defects of such a system, not only as related to the immediate management of certain trying problems of anesthesia but also as related to the development and advancement of anesthesia. I thought I foresaw that the future of better surgery would be intimately linked with the future of better anesthesia—which all now know to be the case.

The development of anesthetists has therefore interested me very much, and it is through it in recent years that we have seen the extraordinary developments in anesthesia. The plan of the past, under which the anesthetist's responsibility consisted almost solely in putting a patient to sleep and in keeping him there until the operation was over, did not attract the most desirable type of minds to this field. When, however, anesthetists were given actual responsibility and even authority, together with an opportunity to develop and expand their clinical judgment and experience—and when proper remuneration became available—real progress began to appear.

With the development of anesthetists and departments of anesthesia, the progress in anesthesia in recent years has been remarkable, and there has been nothing which has given me greater satisfaction. Nothing else has proved so valuable in the way of facilitating and assuring the safety of surgery.

It would be wrong for me to present a discussion of anesthesia and anesthetists, since it would be but a delivery of the views of our anesthetists, Dr. Sise and Dr. Woodbridge. What I can well discuss, however, is the attitude of heads of surgical departments toward anesthetists, some of my personal experiences with them and my reactions as an operating surgeon to some of the anesthetics. I can speak, of course, only from my own experiences in an organized clinic, in which the operations are done always in the same two hospitals with the same unchanging personnel, and with the same unchanging surgical teams. I realize that these conditions are often difficult for some anesthetists, and that modifications are necessary to meet such changed circumstances.

One of the fundamental requirements for good anesthesia and good anesthetists is, I believe, that the latter should have the opportunity and plenty of time to make careful examinations of patients well in advance of the day of the operation. The complete record of a patient's history, physical findings, laboratory data and contemplated surgical procedure should be available for their perusal, in order that they may form an estimate of the patient's condition and the magnitude of the procedure which he is expected to withstand.

The policy of sending patients into the hospital the night before operation and operating on them the next

morning, unless they have been recently and particularly examined and estimated by the anesthetists in the clinic, is, we are convinced, a bad one.' If patients arrive at the hospital between 5 and 7 o'clock of the night before operation, as they not infrequently do, no matter when they are told to arrive, there will often be haste and omissions in preoperative examination. In order that this may not occur, we have for some years maintained the rule that patients who are to have major operations must be in the hospital two nights before operation. This permits leisurely examination and preparation. Any major surgical operation has a sufficient percentage of risk attached to it to justify requiring the patient to give sufficient time for careful approach to it.

We feel that the repeated clinical experiences which anesthetists have with definite operative procedures should be turned to advantage to the patient and the surgeon. We have therefore for some time, at the request of Dr. Woodbridge, arbitrarily grouped all risks into grades 1, 2, 3 and 4, grade 1 being a nearly perfect risk, grade 2 a slightly doubtful risk, grade 3 a dangerous risk and grade 4 a risk in which a fatality is probable. No grade 4 risks should be permitted to continue on the operative list, and the anesthetist and surgeon should carefully discuss the operative procedure, the anesthetic and the probable danger in all grade 3 patients. This plan surrounds the operative procedure with an additional safety measure. All experienced surgeons and anesthetists realize that not infrequently patients are lost by routine procedures and by neglect to observe indications of danger which are not strikingly obvious.

We believe that the anesthetist should see the patient postoperatively in order that he may acquire first-hand information from the patient himself as to his objective and subjective reaction to the anesthetic and operation. Furthermore, it is psychologically important both from the point of view of the patient and from that of the anesthetist that contact between them be reestablished after the operation. The anesthetist has played a real part in it, much more real than surgeons have hitherto acknowledged, and he deserves and appreciates a portion of the patient's friendship and gratitude, just as the surgeons do. All surgeons would do well to realize that, provided men of the right character have been selected, anything which increases the responsibility and elevates the position of anesthetists automatically advances anesthesia.

As the director of a clinic in which a considerable amount of surgery is done, I realize that there is a distinct tendency on my part to influence the anesthetists unduly, and to acquire certain fixed views concerning the relation of anesthesia to operation. For example, during the period when ether was employed almost exclusively for abdominal operations, I personally tended to demand considerable depth of anesthesia with its consequent relaxation and facilitation of exposure and approach to operative fields, a situation which was very properly resisted by the anesthetists, particularly in bad risks, because of the shock reactions. I feel that as regards spinal anesthesia, we surgeons have placed undue demands on our anesthetists, particularly in high spinal anesthesia for upper abdominal operations, because of the fact that this type of anesthesia provides such ideal operating conditions. It has not been easy, I know, for our anesthetists, who consider high spinal anesthesia in bad risks a dangerous procedure, to win us away from this type of anesthesia with its beautiful relaxation, quiet respirations and advantageous exposure, and to make us modify our technic to fit some less dangerous anesthesia, such as avertin and regional and intratracheal ethylene in gastric resections, splenectomies, common duct stone explorations and other upper abdominal operations on patients who are bad risks. Having become adjusted to this type of anesthesia, particularly since the intratracheal method and carbon dioxide absorption have been added to the procedure, and being convinced of the additional safety factor which it provides, particularly in long upper abdominal operations on patients who are poor risks, we have become aware that we must not impose our will on our anesthetists.

Surgeons must, in short, realize that the constantly widening field of anesthesia is playing a very large part in the advance of surgery, and they must listen with respect to the opinions of anesthetists as to the effects of various forms of anesthesia on the outcome of various operative procedures, with a willingness to modify the procedures to meet the dangers of anesthesia.

I am aware that in discussing the question of nurse anesthetists I am touching on a subject concerning which there has been considerable debate among anesthetists. Nevertheless, having, as I do, a conviction that the nurse anesthetist has a distinct place in the problem of anesthesia, I must voice my sentiments in favor of retaining her in the field of inhalation anesthesia. One cannot consider the question of improvements in anesthetists and anesthetics without considering their relation to the costs of surgical care. As I have said, if one is to obtain better anesthesia one must obtain better anesthetists, and this implies of necessity, and quite properly, better salaries for anesthetists. Good anesthetists are well worth good salaries, but it would unduly burden the cost of surgical procedures to employ physician anesthetists for all anesthesias. Nurse anesthetists, working under the guidance and direction of physician anesthetists, attain a considerable degree of technical skill in administering inhalation anesthetics, yet may properly command much lower salaries, and so play an extremely desirable part in reducing the costs of anesthesia and hence the costs of surgical care.

Finally—and I hesitate to raise this question, yet feel that I must, since I am in such an unassailable position from which to discuss it, having no personal ax to grind—the medical profession, realizing as it now does the advantages of expert anesthesia, must take a position against the employment of the consultant physician or family physician as the anesthetist. Since we, working in a clinic, are entirely free from partiality, it is my duty for the benefit of those men who are doing surgery, especially in rural communities, to do everything that I can to help them free themselves from this form of patronage, which today actually amounts not infrequently to a disguised form of fee splitting.

It has become an accepted arrangement, handed down from the ether era, that one of the perquisites of the physician referring a patient to a surgeon is that he is to give the anesthetic if he desires. This custom has been largely overcome in good-sized centers, but many surgeons in less populous ones are suffering from it. They wish to develop better anesthesia and anesthetists, but are fearful of eliminating the prevailing arrangement less they lose their surgical consultants. It will be eliminated only when we discuss it frankly, and when it is made clear to the medical public that such a system does not provide for the patient the best type of anesthesia, an essential feature for his recovery, does not give an opportunity for improvement in anesthesia, does not render to the patient the expert services which the consultant would want for himself or his family and does not permit the surgeon to develop a coordinating and cooperating organization. This is a development which every community needs, and must have if it is not to see an increasing number of its people seeking surgical services in other regions, where such coordination and cooperation exist.

The family physician is the backbone of medicine. He possesses, certainly in this country, a high standard of knowledge, judgment and honesty. I have now for some years given clinics in several of the postgraduate assemblies which occur yearly in all parts of the country. When I see men who have left their general practice to come and spend the better part of a week attending clinics and lectures which not infrequently run from early in the morning to late at night, I am impressed with their high character, and with the spirit which prompts them to take time from an often already overburdened existence in order to seek further knowledge. It is to those men who have naturally accepted the anesthesia perquisite as a legitimate procedure that we must patiently and kindly, but convincingly, demonstrate that it is not the best thing for the patient, for the operations or for anesthesia, and that such a plan hampers advancement in the field of anesthesia—a field which, I take pleasure and satisfaction in admitting, is playing a considerable part in widening and making safer the field of surgery.

RESPIRATORY AND CIRCULATORY CHANGES DURING SPINAL ANESTHESIA

M. H. SEEVERS, M.D.
AND
R. M. WATERS, M.D.
MADISON, WIS.

Respiratory paralysis is the usual cause of immediate death from spinal anesthesia. Three mechanisms, or combinations of these, may be involved:

1. Direct action on the medullary respiratory centers by diffusion of the drug to the fourth ventricle in paralytic concentrations. The observations of Koster and Kasman[1] and of Johnston and Henderson,[2] who demonstrated experimentally that excessively high concentrations are required to bring about this effect, indicate that this type can probably be excluded from serious consideration.

2. Ascending block of the intercostal and phrenic nerves. This type of paralysis is unquestionably preventable and is secondary either to (*a*) ignorance of, or inexperience in, the technical aspects of the procedure, or to (*b*) unsuccessful attempts to produce a selective sensory nerve block of the neck and upper thoracic regions.

3. Insufficient nutrient flow of blood through the central respiratory mechanism secondary to cardiovascular depression. Cardiovascular depression in some degree is attendant on every intradural block involving the upper part of the abdomen and the thorax. Since the integrity of the respiratory center depends on the maintenance of an adequate volume flow of sufficiently oxygenated blood, the obvious inference is that the latter mechanism is responsible for the majority of cases of respiratory failure. We shall attempt to demonstrate that the maintenance of an adequate volume flow of well oxygenated blood is difficult if nerve impulses are prevented from reaching a majority of the costal muscles by a high thoracic block.

A study of the factors concerned in the disturbance of circulation may furnish some evidence as to the possible means of prevention of respiratory failure.

Nearly all authors have stressed paralysis of the splanchnic nerves, with a subsequent pooling of blood in the abdominal region, as the principal, if not the only, factor involved in the circulatory depression. Experimental observations on the dog do not substantiate this view, as bilateral splanchnotomy does not produce the characteristic fall of blood pressure. Kremer and Wright[3] have recently observed that bilateral section of the splanchnic nerves of the cat produces a fall in mean blood pressure of only from 0 to 15 per cent. Furthermore, they found little or no change in venous pressure although the vascular bed in the spleen and intestine was markedly enlarged. The clinical findings of an avascular contracted bowel and blanched uterus indicate that all of the "lost" blood is not in the splanchnic region.

Skeletal muscle tone is essential for the maintenance of a stable capillary and venous bed. Loss of this tone accompanies any intradural block. Undoubtedly the splanchnic area is not the only region in which one can expect an enlarged capillary bed. Plethysmographic records made in this laboratory indicate a considerable increase in leg volume of dogs under spinal anesthesia.

It is of relatively little practical importance whether paralysis of the splanchnic nerves, the vasoconstrictor nerves to the skin and other vessels of the trunk and extremities or loss of skeletal muscle tone is the principal or contributory factor to the circulatory depression. All will admit that a marked decrease in the peripheral resistance to blood flow occurs in the region involved in the block.

Significant, however, is the fact that a sensory and motor block to the tenth dorsal segment, which produces an increased capillary bed over a considerable portion of the body, is usually attended only with a moderate alteration in blood pressure. (Rarely a marked drop in pressure may be due to a motor paralysis higher than is indicated by sensory examination.) Apparently vasoconstriction in other parts of the body or an increased cardiac output can occur as a compensatory measure. Furthermore, adequate oxygenation of blood and normal thoracic activity occurs, since there is no respiratory involvement.

Grave cardiovascular changes occur, as a rule, only in blocks that involve the chest. As the thorax is implicated, two important factors enter into consideration: (1) additional paralysis of the vasoconstrictor fibers and (2) intercostal nerve paralysis.

While the first factor has been elaborated by writers on the subject, little attention has been directed to the

consequence of partial or complete loss of costal respiration when superimposed on a vascular incompetence involving two thirds of the body. Clinicians see patients who suffer no outstanding ill effects from a diminution in minute volume respiration, particularly if this is of short duration. This may explain why the diminished respiratory exchange occurring during spinal anesthesia has been minimized. The conditions that exist during spinal anesthesia deviate markedly from the normal. The increased vascular bed secondary to the aforementioned factors means low blood pressure, diminished minute volume flow of blood and poor oxygenation of tissues. The integrity of the medullary centers and heart is dependent on an adequate supply of oxygen. The additional anoxemia accompanying partial or complete thoracic paralysis may spell disaster.

That the oxygen needs of the body are not adequately met, owing to a reduced volume flow of blood and a decreased gaseous exchange in the lungs proportional to the lowered thoracic excursion, is the contention that constitutes the main thesis of the present communication.

In 1912, Gray and Parsons[4] published a clinical study in which they stressed the intimate relationship existing between the fall in blood pressure and the costal paralysis. Their conclusion—"The main fall is due to the thoracic paralysis, which is not compensated for by overaction of the diaphragm, and consequently the aspiration action of the thorax is diminished"—being at variance with the view of some physiologists concerning the mechanical movement of venous blood by variations in intrathoracic pressure, has not been generally accepted. We believe that their observation was essentially correct. Whether or not we accept their conclusion as to the mechanism involved, the fact remains that a partial or total loss of costal respiration diminishes gaseous interchange.

Isenberger and Lundy[5] observed that artificial respiration accomplished by alternate inflation and deflation of the lungs, with positive and negative intrapulmonary pressure, would maintain a nearly normal blood pressure in dogs after complete paralysis of the spinal cord produced by large doses (2,500 mg.) of procaine hydrochloride intradurally. This observation indicates that the heart will remain competent in spite of the decreased peripheral resistance provided fairly normal thoracic activity and pulmonary interchange occur. This method offers a means of study of the relative importance of the respiratory and cardiovascular factors with which we are concerned under the conditions existing in high spinal block. Accordingly, we have employed a similar method, a brief outline of which follows.

METHOD

Large dogs were used as the experimental animals. They were anesthetized three hours before the experiment with sodium barbital, 250 mg. per kilogram intravenously. An initial mean blood pressure of from 140 to 170 mm. of mercury and good respiratory activity were assured by this method. A few controls with ethylene and others with local infiltration to accomplish the operative procedures indicated that barbital modifies the end-result but slightly, provided sufficient time (three hours) is allowed after the injection before beginning the experiment. Removal of one spinous process or partial laminectomy was performed to insure intradural block.

The animal was then placed in a small Drinker respirator. This apparatus offers an ideal mechanical means of simulating normal costal respiration besides serving as a body plethysmograph to record respiration. Unobstructed respiration was assured by either a tracheal cannula or a closed endotracheal catheter. Thirty-seven animals were utilized, the procedure being to induce a block with procaine hydrochloride or to section the cord at various levels and accomplish as many of the following observations as were compatible with the technic involved:

(*a*) Cardiovascular data: heart rate, pulse pressure, mean arterial pressure, right auricular and iliac venous pressure and leg volume.

(*b*) Respiration: rate, amplitude, type, minute volume exchange, intra-abdominal and intrapleural pressures, alveolar oxygen and carbon dioxide, blood oxygen and carbon dioxide and oxygen consumption.

(*c*) Treatment: artificial respiration, oxygen, carbon dioxide, position, pressure on body and various pressor and stimulant drugs.

As the limitations of the present paper will not permit detailed experimental data,[6] we have chosen to consider individually each of the foregoing factors, attempting to correlate the laboratory findings with data gathered from about fourteen hundred clinical cases from the anesthesia service of the Wisconsin General Hospital.

OBSERVATIONS

Cardiovascular Data.—The tendency of the heart rate to remain relatively slow in either low or high blocks is well known clinically. The dog usually exhibits a tendency to vagotonia, particularly if the block is high. The relatively slow heart seen clinically allows an increased diastolic filling and a relatively large stroke volume provided the integrity of cardiac muscle is not impaired by myocardial disease or anoxemia secondary to chronic anemia, extensive hemorrhage, etc. Clinically, a rapid heart during spinal anesthesia is a danger signal and usually follows a diminished blood volume secondary to hemorrhage. It is serious and demands an immediate replacement of the original circulating volume. This condition is readily produced in dogs by hemorrhage.

The fall in systolic pressure is directly proportional to the height of the block. A lowered diastolic pressure is the rule, since it is a measure of the peripheral resistance to blood flow. In laboratory and clinical cases involving the thorax untreated by pressor drugs, a small pulse pressure usually obtains. Although the diminished pulse pressure is a rough indication of a diminished cardiac output, it appears from both laboratory and clinical observations that this condition may exist without observable deleterious effects until the cardiac muscle begins to fail from lack of sufficient oxygenation. Burch and Harrison[7] have demonstrated that there is little reduction of cardiac output in dogs under spinal anesthesia until the mean arterial blood pressure falls to 40 or 50 per cent of its original value.

The conception prevails that in consequence of a pooling of blood in the splanchnic region, there exists an ineffective filling pressure on the right side of the heart. Study of the venous pressure of dogs obtained directly by introduction of a cannula through the right external jugular into the right auricle indicates that a rise in venous pressure usually occurs, which is proportional to the fall in mean arterial pressure (fig. 1). A rise in venous pressure in the iliac vein also occurs. If the total blood volume is diminished by hemorrhage, however, a fall in venous pressure in the right auricle is observed. The prevailing opinion of cardiologists is that the output of the heart per minute is largely dependent on the effective filling pressure and heart rate provided the integrity of cardiac muscle is unimpaired. Since under these conditions as great or a greater effective filling pressure exists, it becomes obvious that the weak point in the system is the heart itself.

To be effective on cardiac output, this increased pressure in the right auricle must be transmitted from the right side of the heart through the capillaries of the lungs to the left side of the heart. Drinker and his collaborators[8] have shown that the capillaries of the lungs are subject to remarkable increases in capacity by passive distention. If the left side of the heart is failing as a result of anoxemia, it necessarily follows that there will be an increase in the capacity of the lungs for blood and a decrease in their capacity for air. If these assumptions are accepted, it becomes obvious that a considerable portion of the circulating blood may be congested in the pulmonary vessels.

The conception held by some writers, that spinal anesthesia confers on the heart a period of physiologic rest, because the heart is relatively slow, appears to us to be as illogical as to assume that acute anemia or acute cardiac decompensation relieves the cardiac muscle of its normal load of work.

It is well known that a decreased venous pressure exists at the right side of the heart during shock of hematogenic origin.[9] It has been generally accepted that this observation is applicable to spinal anesthesia. The origin of shock in spinal anesthesia is initially entirely neurogenic. Many a clinician has compared in his mind the case of spinal anesthesia with a blood pressure so low as to be barely recordable, with the case of shock following hemorrhage, and wondered why the same type of resuscitory measures revived the former and failed in the latter. We must seek the answer in the knowledge that a diminution of total circulating blood volume with a loss of the integrity of the vessel walls as regards fluid and blood proteins occurs in hematogenic shock. It becomes apparent that this condition does not exist in the average case of spinal anesthesia. That prolonged spinal anesthesia may cause such a result, and that it may be superimposed on spinal anesthesia are well known. It is likewise well recognized that it is poor surgical judgment to superimpose spinal anesthesia on an existing shock following extensive hemorrhage. This was well demonstrated in the war experience of Marshall,[10] who observed that the mortality after spinal anesthesia occurred in the group of cases in which hemoglobin was below 100 with the Haldane hemoglobinometer.

Respiration.—Experimentally, the efficiency of respiration, thoracic excursion and minute volume exchange decreases in blocks involving the thoracic region. This decrease is proportional to the height of the block. In general, the same alterations are seen clinically. Compensation by increased diaphragmatic activity may occur in the low thoracic blocks. Although this overactivity of the diaphragm increases with high thoracic blocks, it is less effective in maintaining a good pulmonary ventilation. This overactivity of the diaphragm is hindered and rendered inconspicuous in the Trendelenburg position owing to the pressure of the abdominal viscera. That pulmonary ventilation is decreased is further evidenced by our studies of alveolar and blood oxygen and carbon dioxide, both in man and in dogs. A considerable decrease in alveolar, as well as in arterial and venous blood oxygen occurs, with a corresponding increase in carbon dioxide. Oxygen consumption in dogs rises and falls with the changes in arterial pressure. We interpret this as an indication of a diminished volume flow of blood rather than a diminished utilization of oxygen. Greene and Greene[11] emphasized that in experimentally produced anoxemia little change in utilization of oxygen occurs until the arterial saturation falls to a very low point, provided the blood pressure is unaltered. The saturation of arterial blood, however, varies directly as the circulating volume passing the pulmonary epithelium. Thus, a greater undersaturation of arterial and venous blood and a decrease in total oxygen consumption indicate a diminished volume flow of blood.

Further evidence of the decrease in pulmonary ventilation is furnished by studies of intrapleural pressure variations. The normal intrapleural variations in the barbitalized dog are from an inspiratory pressure of —12: —18 cm. of water to —4: —5 cm. of water during expiration (fig. 1). With a complete paralysis of costal respiration, these variations are reduced to —10: —12 during inspiration and —8: —10 during expiration.

The mean intra-abdominal pressure under these conditions normally varies from —2 to +3 cm. of water, with a respiratory fluctuation of from 0.5 to 1 cm. of water. We have always observed an increase in mean intra-abdominal pressure, as well as in respiratory fluctuation, following paralysis of costal respiration. The changes are probably largely due to increased diaphragmatic activity. These findings are contrary to the ideas of Gray and Parsons, who believed that a decreased intra-abdominal pressure existed secondary to flaccid paralysis of the abdominal musculature.

Treatment.—From the foregoing observations, we have gained the impression that the extremely close relationship existing between oxygenation of tissues and the maintenance of good cardiovascular function must be exceedingly important in spinal anesthesia. Experiments to study this relationship further were therefore performed, with the following results:

1. Artificial respiration alone, with the Drinker respirator, using alternate positive and negative pressures, will maintain the blood pressure near its original level after either a block completely paralyzing all respiratory activity or section of the cord at the corresponding level (fig. 2). These observations agree with those of Isenberger and Lundy. Either negative pressure or positive pressure alone, while sufficient to sustain life, is not so effective in maintaining a good arterial blood pressure. The same applies to chest compression or positive intrapulmonary pressure.

2. Exposure of the epithelium of the lungs to high concentrations of oxygen markedly augments the beneficial effects of artificial respiration.

3. Passive distention of the lungs with 100 per cent oxygen will maintain an adequate blood pressure in the absence of any respiratory movement for at least fifteen minutes (fig. 3). Apparently the only limitation to the procedure is the accumulation of carbon dioxide in tissues.

4. Inhalation of carbon dioxide in 5 and 10 per cent concentrations in oxygen always resulted in further lowering of the blood pressure in the animal with a low blood pressure accompanying thoracic paralysis. These inhalations were beneficial, however, in hastening a return of intercostal activity in the animal in which thoracic function was beginning to return at the termination of the block.

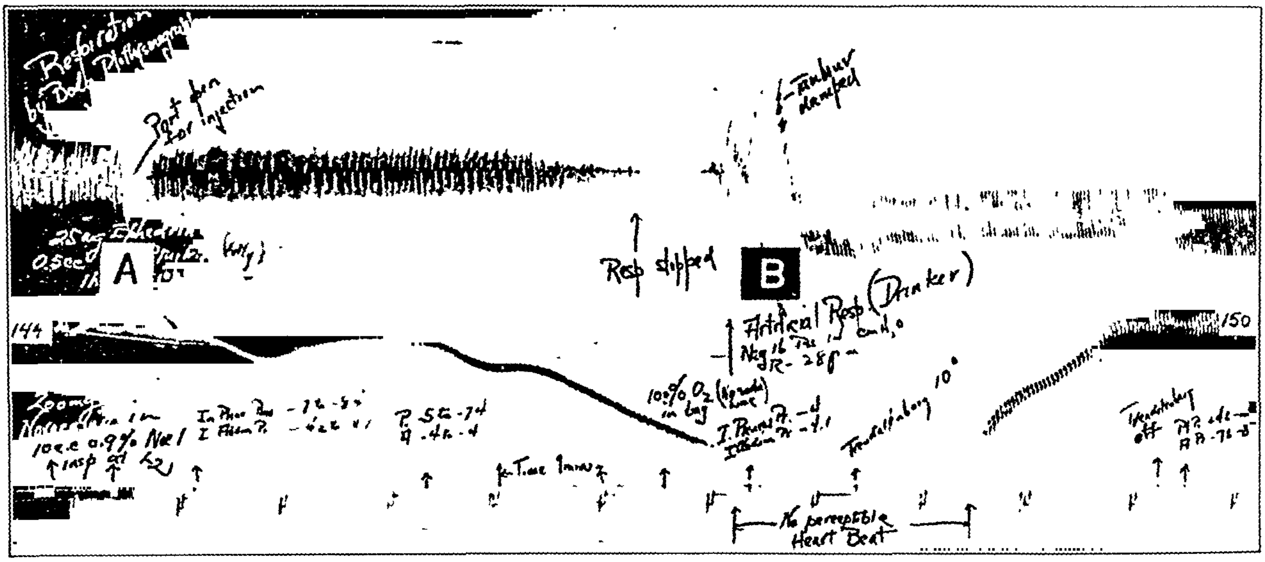

Fig. 2.—*A*, mean arterial blood pressure, 144 mm. of mercury. Intraspinal injection (L_2) of 200 mg. of procaine hydrochloride in 10 cc. of physiologic solution of sodium chloride. (Note the primary respiratory paralysis.) *B*, artificial respiration with the Drinker respirator. Breathing 100 per cent oxygen. No cardiac impulse to mercury manometer for two minutes. Ten degrees Trendelenburg for two minutes. Mean arterial blood pressure, 150 mm. of mercury five minutes after artificial respiration.

In view of these observations, there can be little doubt as to the validity of our original premise. Unquestionably the cardiovascular system will remain competent even though peripheral resistance to blood flow has been reduced to a minimum by paralysis of all vasomotor nerves and skeletal muscle, provided the volume of adequately oxygenated blood retained within the vascular boundaries is sufficient to keep up an effective circulation to the vital organs. This knowledge makes it easier to study therapeutic procedures rationally. Four methods of approach suggest themselves to combat the altered physiologic conditions. All have been clinically utilized. They are:

1. Increase of the easily available oxygen of the blood by exposure to high alveolar oxygen percentages or artificial respiration.

It seems reasonable that every patient under spinal anesthesia should be given the benefit of inhalations of oxygen. This conception is verified by clinical as well as laboratory observations. Patients are more comfortable, less nauseated, maintain a better blood pressure and have a better postoperative recovery following the exhibition of oxygen during the surgical procedure. This is particularly true if sedatives in sufficient quantities to produce any respiratory or circulatory depression have been administered prior to the block.

It is not generally recognized clinically that any significant increase in available oxygen can be assured by the inhalation of oxygen. Sollmann[12] gives the following figures: Arterial blood contains about 18.5 per cent of oxygen in chemical combination with hemoglobin and 0.6 per cent dissolved in plasma, a total of 19.1 per cent. Inhalation of undiluted oxygen increases the percentage of oxyhemoglobin only to 18.7 per cent; the dissolved oxygen is increased in proportion to the partial pressure, i. e., to 3 per cent, giving a total of 21.7 per cent, or an increase of 2.6 per cent. Since oxyhemoglobin does not readily yield all of its oxygen to tissues, Haldane[13] considered that this apparently small increase really equals about 40 per cent of the easily available oxygen of the blood. In consideration of the diminished minute volume flow of blood accompanying spinal anesthesia, it appears that this increase may be quite significant.

[13] Haldane, J. S.: Respiration, New Haven, Conn., Yale University Press, 1922.

From our observations on dogs, the simultaneous administration of carbon dioxide in the cases of impending respiratory paralysis secondary to low blood pressure is of no benefit. On the contrary, a lowering of blood pressure occurs. Since the central stimulant action of carbon dioxide depends on a fair oxygenation of medullary centers and its effectiveness on intact vasoconstrictor pathways, these results might be expected in high blocks. Apparently, a concentration of carbon dioxide that will stimulate the depressed respiratory or vasoconstrictor centers cannot be reached without exerting a predominant paralytic effect on the peripheral blood vessels.

Should respiratory paralysis supervene, whether due to direct nerve block or secondary to cardiovascular incompetence, artificial respiration must be resorted to. The two phase type comprising forcible inspiration and expiration is preferable. Although this is best administered by mechanical devices, such as the Drinker respirator, it can be readily accomplished by a modification of the Schäfer method, pressure on the chest being used to effect expiration and compression by a second operator of a distended oxygen-filled bag fitted to a face mask to insure good inspiration. The latter procedure alone will suffice, as the lungs are distended with only slightly diluted oxygen. Overdistention of the bag is to be avoided, as compression of the pulmonary vessels prevents an adequate flow of blood to the left ventricle. It seems reasonable that a moderate distention, however, may be beneficial by relieving pulmonary congestion, thus making more blood available for systemic circulation. Obviously, a good airway is imperative. This can best be assured by pharyngeal or endotracheal intubation. The stomach may be easily inflated if positive pressure is applied to a bag attached to a face mask. This distention will contribute to the circulatory embarrassment and can be avoided by an endotracheal catheter.

It is likely that the Drinker respirator acts as a mechanical aid to circulation by pressure on the extremities, abdomen and chest (fig. 4). This constitutes the ideal method of treatment, since no intubation is necessary and no gastric inflation is possible.

2. The use of drugs to effect an increase in peripheral resistance or an increase in cardiac output.

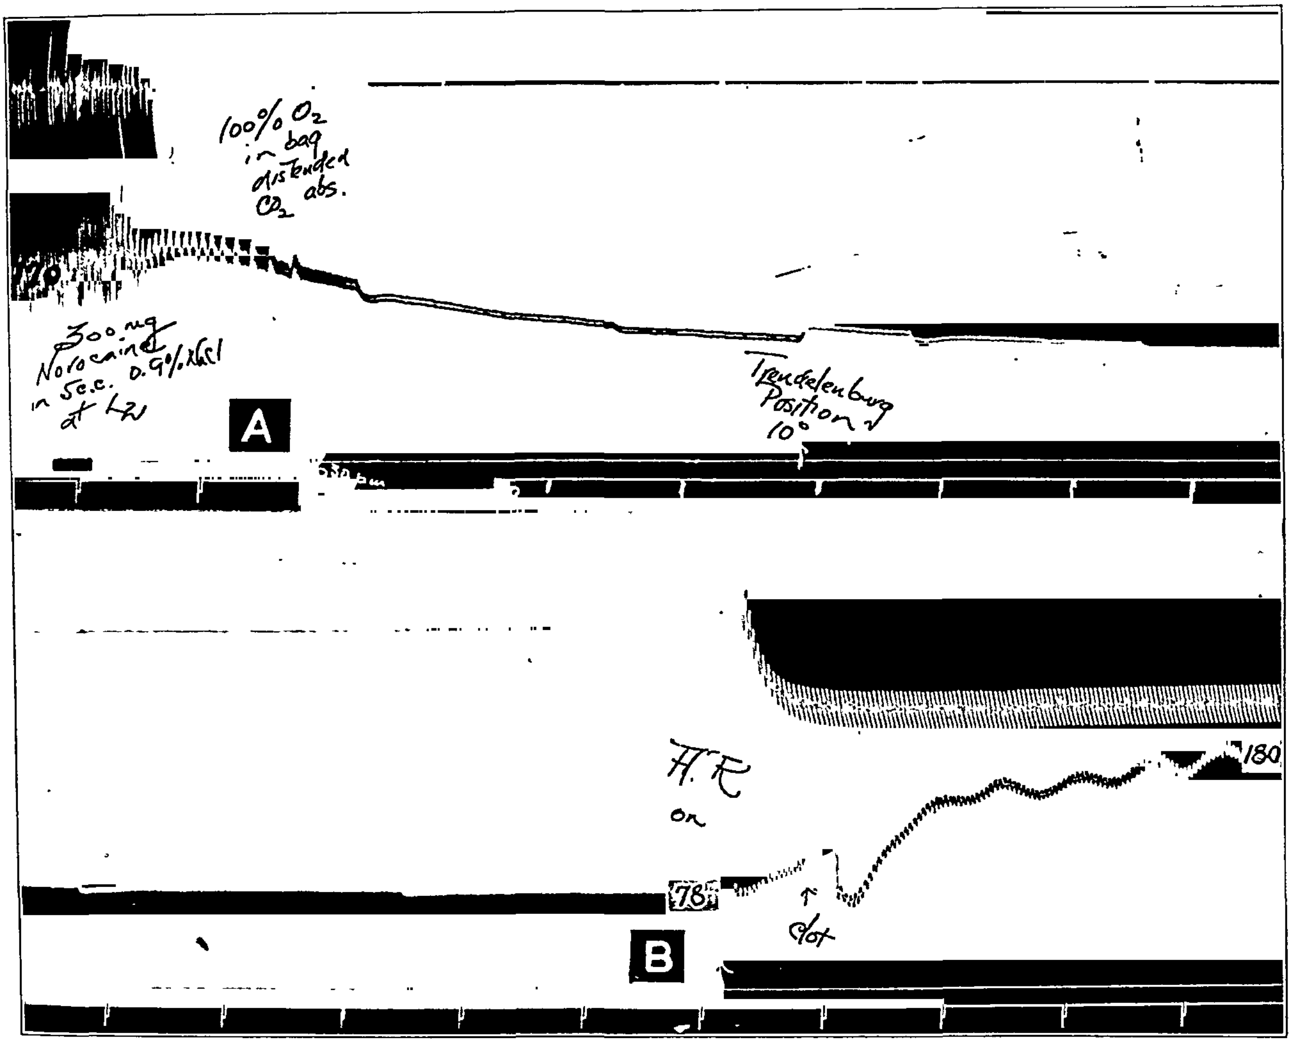

Fig. 3.—Upper tracing: *A*, mean arterial blood pressure, 170 mm. of mercury. Intraspinal injection (L_2) of 300 mg. of procaine hydrochloride in 5 cc. of saline solution. Immediate costal and phrenic nerve paralysis (upper line). The lungs expanded with 100 per cent oxygen. Lower tracing: *B*, mean arterial blood pressure, 78 mm. of mercury. There has been no respiratory movement for sixteen minutes. Artificial respiration with the Drinker respirator. Five minutes later, the mean arterial pressure was 180 mm. of mercury.

The drugs commonly employed at present are epinephrine and ephedrine. That the first is worthless for the prolonged maintenance of blood pressure is evidenced both in the laboratory and in the clinic. It may be of value, however, in cases of sudden circulatory collapse as a temporary expedient until the effects of some longer acting drug may be attained. The prolonged intravenous infusion of dilute solutions may also be effective.

Ephedrine has received an extended clinical trial in spinal anesthesia since first advocated by Ockerblad and Dillon,[14] given either prophylactically prior to the block or intravenously after the block. Evidence from both the clinic and the laboratory indicates that its continued use is warranted. These observations also lead to certain definite conclusions regarding its use.

The effectiveness of ephedrine appears to be due to its ability to (*a*) increase the peripheral resistance by constricting arterioles and (*b*) increase the minute volume output of the heart by direct action on the cardiac muscle.[15] It is well known pharmacologically that the efficacy of drug stimulation depends on the physiologic state of the cell to be stimulated. Ephedrine is no exception to this rule. The anoxemic heart and the blood vessel, the permeability of which to fluids and proteins is increased from oxygen deprivation, cannot be expected to respond. For this reason, ephedrine is a disappointment in shock of hematogenic origin. This is a common clinical observation. Chen[16] has demonstrated the relative impotence of ephedrine in combating this type of shock in dogs. Our laboratory observations confirm this finding. Cases of spinal anesthesia have been reported in which disastrous results have been laid to repeated relatively large doses of ephedrine. We have observed that the effectiveness of ephedrine in the dog following intradural block is in inverse relation to the degree and duration of low blood pressure and anoxemia.

The use of large doses of ephedrine to maintain a blood pressure higher than normal throughout the

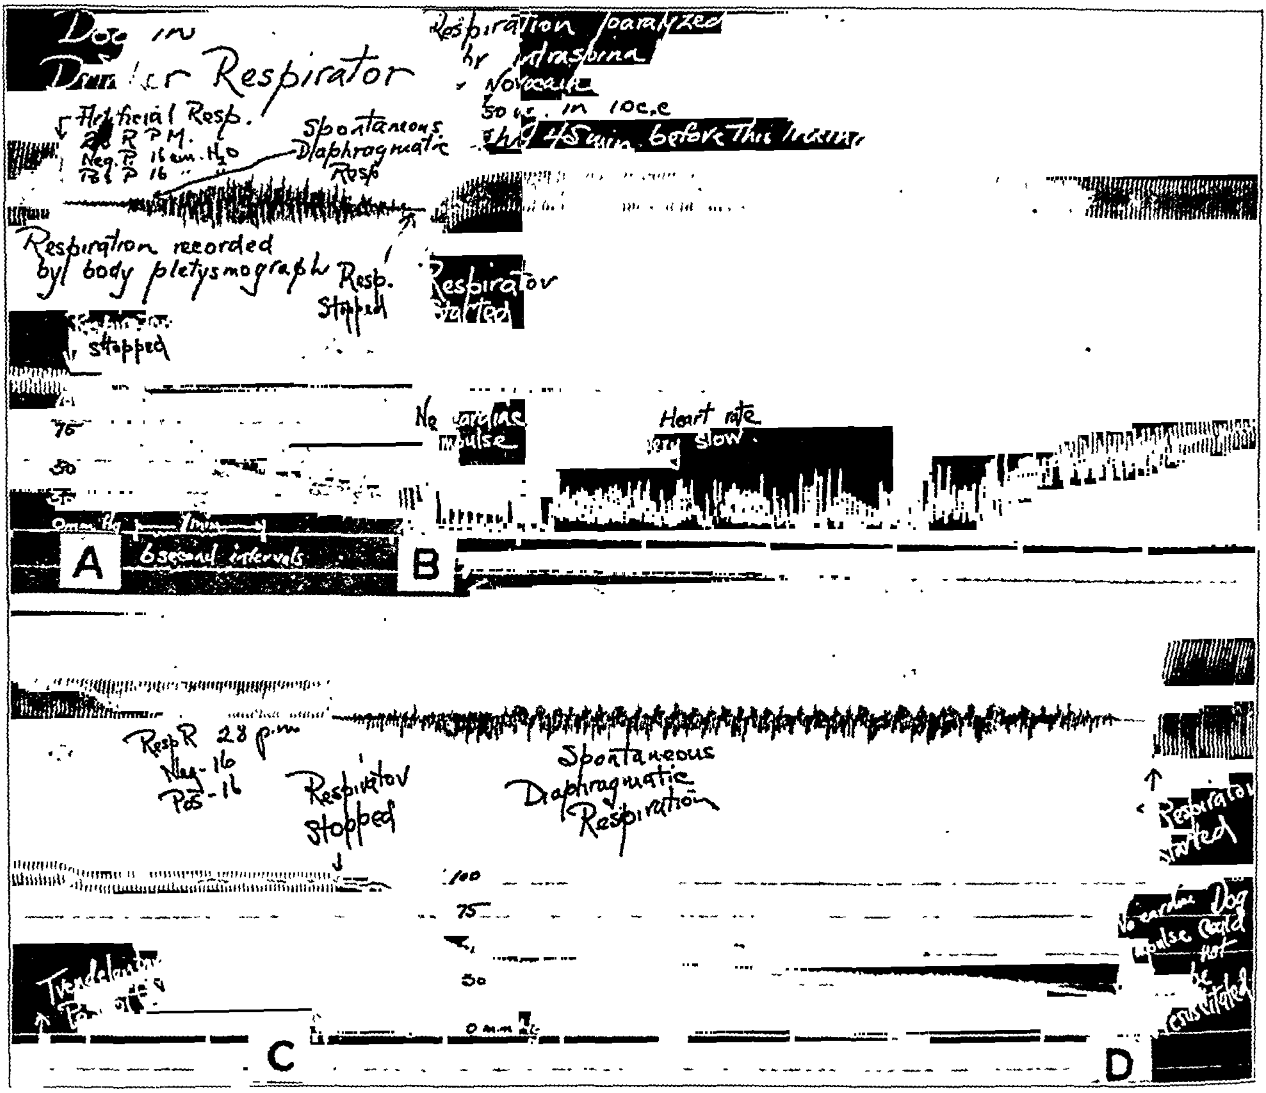

Fig. 4.—Upper tracing: The dog had been artificially respired for one hundred and sixty-five minutes following the intraspinal injection of 400 mg. of procaine hydrochloride in 10 cc. of 0.9 per cent saline solution. Blood pressure, 100 mm of mercury: *A*, respirator stopped. Note that spontaneous diaphragmatic respiration is not adequate. *B*, respirator started. Heart rate 15 per minute. Blood pressure 30 mm. of mercury. Lower tracing: Twenty minutes after upper record. *C*, respirator stopped. Note again that spontaneous respiration is inadequate. *D*, respirator started. Could not be resuscitated after six minutes, with blood pressure at 30 mm. of mercury.

operative procedure may mask for a period the symptoms of impending shock of hematogenic origin. When the overstimulation resultant from drug action subsides, circulatory collapse may occur, which, had it been recognized and treated early by fluid or blood replacement, might have been averted. Its marked cardiac action indicates discretion in its use when cardiac disease is known or expected. We have seen no evidence of circulatory or other damage from ephedrine in cases of uncomplicated spinal anesthesia if the dose is limited to that sufficient to restore normal blood pressure, provided the tissues are adequately oxygenated.

3. The use of position to favor gravitational circulation.

The efficacy of this procedure in the prevention of medullary paralysis has been demonstrated clinically. That it may have some disadvantages besides hindering surgical manipulation in the upper part of the abdomen has not been stressed. The weight of the abdominal viscera tends to compress the contents of the thorax, particularly in the exaggerated Trendelenburg position. Experimentally, there occurs an increase in venous pressure in the right side of the heart. There is no evidence from laboratory experimentation that the cardiac output is materially increased, although a slight rise in blood pressure occurs. The failing heart may allow an increased volume of blood in the pulmonary vessels and a diminished vital capacity. Hamilton and his co-workers[17] have recently reiterated the well known fact that a marked decrease in the vital capacity occurs even in the recumbent position. If these facts are accepted, we may postulate that certain portions of the lungs will remain in a state of relative atelectasis. This is particularly true if expansion of the lungs is further hindered by thoracic paralysis. In view of this reasoning, it seems possible that the Trendelenburg position may be a factor in the etiology of postoperative pulmonary complications.

*Pulmonary Complications in Fourteen Hundred Cases of Spinal Anesthesia in the State of Wisconsin General Hospital**

	Operations on Upper Part of Abdomen	Operations on Lower Part of Abdomen	Extra-Abdominal Operations
Cases	351	571	484
All respiratory complications (until time of discharge from hospital)	82 (23.3%)	113 (19.8%)	24 (5.0%)
Severe respiratory complications	22 (6.2%)	27 (4.7%)	11 (2.2%)
Deaths	14 (3.9%)	8 (1.4%)	9 (1.8%)

* Through Dr. Martha Kohl.

Sise,[18] of the Lahey Clinic, stated in his report of the incidence of postoperative pulmonary complications his belief that the type of operation and the preoperative condition of the patient are more important factors in the production of these complications than the type of anesthesia. He found, to his surprise, that the number of complications following spinal anesthesia was in the same order of magnitude as with ether anesthesia.

Statistics of pulmonary complications in fourteen hundred cases of spinal anesthesia in the State of Wisconsin General Hospital are available (table).

Unfortunately no statistics on general anesthesia are yet available under conditions existing in this hospital. Other authors, on the contrary, apparently have been more fortunate. This is due, perhaps, to a greater skill in technic, a better selection of risks or such an enthusiasm for the procedure that postoperative complications are looked for only at the autopsy table or are ascribed to causes other than spinal anesthesia.

4. Increase in the total volume of circulating blood. If one assumes that during the early stages of spinal anesthesia the permeability of the vessel wall is unaltered and the original blood volume remains intravascular, then measures that will increase the total volume might be expected to effect a beneficial influence on pressure.

Burch and Harrison[19] found that the injection of rather large amounts of physiologic solution of sodium chloride prior to intradural block in dogs was quite effective in preventing the marked fall in blood pressure.

If the method is to be of the most benefit, obviously it must be utilized while the vessels are still physiologically intact. This means either prior to, or throughout the course of the operation.

If spinal anesthesia happens to be the method of choice for operation on a patient who is a poor risk, we follow the practice of using a slow intravenous drip, which is started immediately after the block has been induced. Intravenous medication is then instantly available.

COMMENT

In view of experimental and clinical observations, we believe that too little stress has been placed on the rôle of respiration in the maintenance of cardiovascular integrity during spinal anesthesia. Our conception of the train of events occurring during untreated high spinal block is as follows: initial decrease in peripheral resistance to blood flow by vasomotor nerve and skeletal muscle paralysis; decrease in minute volume respiration accompanying intercostal nerve paralysis; inadequate oxygenation of blood; diminished minute volume blood flow; progressive loss of vascular tone over the whole body and acute cardiac incompetence, both the result of oxygen deprivation; failure of the medullary respiratory mechanism as the nutrient flow of blood becomes inadequate, the latter occurring while the heart is still capable of being revived by oxygenation.

We believe that the rational use of spinal anesthesia with maximum safety to the patient implies the following:

1. Proper selection of risks, the deciding factors for its use being the absolute need for complete muscular relaxation and the ability of that particular patient to oxygenate his tissues normally. This, of course, precludes the routine use of spinal anesthesia for all patients with abdominal conditions. With spinal anesthesia, as well as with any other anesthetic procedure, individualization must replace "rule of thumb" practice.

2. Limitation of the block to exclude major thoracic involvement. Enthusiasts[1] for the procedure have advocated spinal anesthesia for operations on the head and neck. Any method dependent for its factor of safety on a selective paralysis of sensory as opposed to motor nerves, especially when the motor components are the phrenic nerves, deserves little consideration. This is particularly true in view of the technical diffi-

culty inherent in the exhibition of a selective drug concentration to the nerve components concerned. This difficulty is apparent in the experience of the proponents of the method. A blood pressure so low as to require palpation of the abdominal aorta to determine whether the heart is still active is hardly compatible with what is ordinarily considered to constitute good anesthesia.

3. To combat cardiovascular collapse by the judicious use of the following: Inhalation of oxygen throughout the surgical procedure; the prophylactic or therapeutic use of ephedrine to maintain the original blood pressure (we believe that the patient who might be damaged by moderate doses of ephedrine is not a suitable risk for spinal anesthesia); the use of a moderate Trendelenburg position when indicated, and the proper administration of fluid while the blood vessels and heart still maintain their physiologic integrity. We do not intend to imply that in every case in which spinal anesthesia is used the patient needs or should have all this treatment.
4. Artificial respiration with undiluted oxygen in impending circulatory or respiratory failure.
5. Postoperative hyperventilation with carbon dioxide periodically throughout the first twenty-four hours to expand atelectatic portions of the lungs.

ADVANCES IN ANESTHESIA FROM THE STANDPOINT OF THE ANESTHETIST

JOHN S. LUNDY, M.D.
ROCHESTER, MINN.

One cannot consider advances in anesthesia from the standpoint of the anesthetist without making at least some reference to older anesthetic agents and to the methods of their administration. Chloroform and mixtures containing chloroform continue to fall more and more into disuse, although from time to time its employment is advocated by those who are skilled in its administration.[1] The use of ethyl chloride, other than as an agent for anesthetizing tissue by freezing, has been debated, especially from the standpoint of safety. There are satisfactory ways of inducing anesthesia without ethyl chloride.[2]

Ether, though still widely used by the open drop or semi-open drop method, is becoming less acceptable when so administered than when it is mixed with the gases. Ether given by rectum is being replaced by tribromethyl alcohol (avertin) or tribromethyl alcohol and amylene hydrate. This seems to be an advance. When anesthesia is produced by ether given rectally, it is less easily controlled than when it is given by inhalation. As more and more patients are anesthetized with tribromethyl alcohol, it is being shown that a dose large enough to produce anesthesia should seldom be used. Tribromethyl alcohol tends to be used more and more as a preliminary medicament, to be followed by a local anesthetic or by a general anesthetic given by inhalation in a reduced dose.

Nitrous oxide continues to be the most generally popular gas anesthetic agent, especially for extraction of teeth. This is due largely to the fact that it is not inflammable, and for that reason can be used with more safety than an inflammable gas. Ethylene is widely used and has been generally satisfactory. Its introduction in 1923 marked one of the most outstanding advances in anesthesia in recent years.[3] There have been a few accidents due to its inflammability, and no doubt there will be more unless the generally recognized precautions incident to its use are observed. There are phases of the technic of using this agent that I wish to call to your attention. In addition to maintaining a high humidity and using grounding devices for the gas machine and other furnishings in the operating room, it is well to begin anesthesia with nitrous oxide and oxygen and then to substitute ethylene for the nitrous oxide. At the termination of anesthesia all ethylene and ether are, or should be, flushed out of the machine with a mixture of nitrous oxide and oxygen, regardless of whether carbon dioxide has been used.

Carbon dioxide has been used to produce anesthesia, but its best application is not as an anesthetic but for the purpose of regulating the depth of respiration.[4] This has been a distinct advance in dental, surgical and medical cases. The use of carbon dioxide diluted with nitrous oxide, ethylene or oxygen frequently has helped to control nausea and vomiting in cases in which general or spinal anesthesia has been used. It has been used to advantage in the control of postoperative and nonoperative cases of hiccup, and in some cases its use has made possible the avoidance of straining during gas anesthesia, without the use of ether in addition to the anesthetic gases. When ether is used for admixture, carbon dioxide facilitates the absorption of ether and hastens the induction of satisfactory anesthesia.[5] I think that the postoperative administration of carbon dioxide and oxygen for hyperventilation is a distinct advance in lessening postoperative pulmonary complications.

Magill[6] has made a revolutionary change in methods by his advocacy of intratracheal anesthesia. Formerly, small, hard catheters were used, through which the anesthetic agent was insufflated. Recently, Magill has introduced the use of large, soft rubber tubes through which the patient may inhale or through which the anesthetist may insufflate not only the anesthetic, but also oxygen. Flagg[7] also has demonstrated the efficacy of the large caliber tube. The intratracheal method is particularly useful in intrathoracic surgery, in plastic and other operations on the head and in any operation in which difficult respiration or the posture of the patient makes the administration of a general anesthetic agent by the usual methods more difficult than when the tube is used.[8] Skilful insertion of the large, soft rubber tube eliminates much of the criticism of the method, and gives the anesthetist positive con-

trol of anesthesia and ventilation; obviously it is a distinct advance, especially when methods of inhalation are otherwise difficult. Magill's intratracheal tube has been used in certain cases in which obstructed respiration has complicated other conditions, such as convulsions and swelling or tumors of the throat and neck, or in medical cases in which artificial respiration must be carried on for several hours.

There has been great advance in the methods of administering local anesthetics, and this type of anesthesia continues to be used extensively, especially when patients constitute bad risks. Regional methods of anesthesia are useful if the technic of their application has been mastered; for example, sacral block for operations on the anus and for perineal operations on the rectum is usually the method of choice, as is field block for operation for bunions. Surface anesthetics in ointments, gels and solutions have a definite field in the relief from pain of open wounds and are innovations of merit. The application of a local surface anesthetic agent in the postoperative period, instead of a general analgesic such as morphine, gives, comparatively at least, as much increased benefit as can be derived, in operation, from the use of a local anesthetic rather than of a general anesthetic.

Spinal anesthesia has been and is widely used. It is most useful in cases in which relaxation is essential. It has been abused in some cases by giving the patient an overdose. The principal advance in respect to dosage has been the estimation of it not in terms of milligrams or grains, but in terms of so many cubic centimeters of a solution of a certain concentration. Prepared solutions of local anesthetics are more convenient to use than other preparations. They are relatively safe for operations below the umbilicus,[9] but they are not so safe for operations in the upper part of the abdomen. Many papers have been written about the clinical application of spinal anesthesia, but less is actually known of the underlying physiologic effects, especially among patients who constitute bad risks, than is known of any other method of anesthesia. Ephedrine, by its elevating effect in blood pressure, no doubt has increased the use of spinal anesthesia; in most instances, ephedrine will counteract the fall in blood pressure that is caused by procaine hydrochloride.[10]

Whatever advance is presented by spinal anesthesia comes about through the use of relatively safe anesthetic agents, and no safer one has yet been introduced than procaine hydrochloride. Recently, local anesthetics of more prolonged action than procaine have been introduced, but as yet no agent with less toxicity has been presented or developed. If an agent can be developed which is a local as well as a surface anesthetic and no more toxic than procaine hydrochloride, it will be a real advance. Pitressin has been suggested as a substitute for epinephrine in local anesthesia.[11] If untoward systemic effects can thus be eliminated and the local hemostatic effect retained, this will also be an important advance.

Medication preliminary to operation has been widely used and abused. Whereas a mild effect is desirable, a profound effect is undesirable. This usually applies to morphine, the barbiturates and tribromethyl alcohol. Preliminary medication should be begun from three to twelve hours before operation, with the idea of eliminating fear and apprehension, and ordinarily not for the purpose of producing analgesia. In surgical cases, drugs of relatively short action that produce sedation are better than hypnotics of longer action. A recent advance in this field is the development of pentobarbital sodium, which, like other barbiturates, is antispasmodic, and for this reason, as well as for purposes of sedation, is advantageously given before the administration of local anesthetics. Tribromethyl alcohol has given considerable satisfaction in the hands of many, but the tendency at first was to give it as an anesthetic, later to give it as a basic anesthetic, and finally, still further reduction of the dose tended to place it in the category with the combination of barbiturates and morphine, by its use more as preliminary medication than as an anesthetic agent.

One improved method in procedures of anesthesia has been designated by the term "balanced anesthesia" wherein one uses small doses of preliminary medicaments and general or local anesthetics.[12] This procedure is particularly valuable to the patient who constitutes a bad risk, and from the standpoint of such patients it marks a decided advance in anesthesia.

In surgery and obstetrics there is little excuse for the adoption of any method as a routine. From the standpoint of the anesthetist, the principal advance in anesthesia has been that many agents and methods are available, and that a safe and satisfactory method or agent can be chosen for almost any type of patient or operation.

Medical cases sometimes offer a field in which an anesthetist may contribute to correct diagnosis or better care of the patient. For example, in tetanus, the intravenous use of the barbiturates, alternating with morphine and magnesium sulphate, has given relief to patients whose symptoms would otherwise have been resistant to control. The contribution has been not to the cure of the disease so much as to the control of symptoms.[13] In asthma, the use of oil-ether by colon has at times apparently been a life-saving measure, when the asthmatic condition has become otherwise uncontrollable.[14] In almost any condition in which convulsions are difficult to control, the barbiturates have been found to be useful; for example, in strychnine poisoning, eclamptic convulsions of pregnancy and meningitis. In certain cases in which pain is most difficult to control, the enduring effects of the barbiturates in large doses have controlled otherwise intolerable pain. Examples are industrial accidents, fatal burns or crushing injuries. The control of pain in war is being studied, and the barbiturates offer a method toward that end. Whereas previously the anesthetist limited himself to the administration of general anesthetics, the present-day anesthetist must be familiar with local anesthetics, hypnotics and analgesics, and must be prepared to supervise treatment by oxygen and other vapors, intravenous treatment or any other method of treatment in which he may be of help to his associates. In cases in which the differential diagnosis is essentially related to the determination of paths of transmission of pain, the diagnosis may be aided by the blocking of nerve trunks to certain regions.[15] In certain nonoperative conditions the anesthetist seems to be the one most fitted to make injections of alcohol for its prolonged effect in control of pain.[16] A recently developed anesthesia study record, including as it does a careful postanesthetic and postoperative check on complications, will in time give facts on which to base definite opinions. Previous records, for the most part, give a basis for impressions only.

In recent years the anesthetist has been given new tools and new substances to use, and he has received valuable support from others, both within and without the medical profession.

Pharmacologists, physiologists and chemists have investigated in their laboratories, and have published results concerning various anesthetics and their effects, and these have been outstanding contributions from the standpoint of the anesthetist. General debility makes the choice of the anesthetic more important than it would otherwise be. In general, from the standpoint of the anesthetist, the greatest advance is the tendency to add the science of anesthesia to the art of anesthesia. As Jevons said "Science teaches us to know, and an art, to do."[17] By the science of anesthesia, then, I mean knowledge of the facts, principles and developing laws of anesthesia as they relate to the known facts of chemistry, pharmacology, physiology and other fundamental medical sciences. The art of anesthesia is the skilful application of this knowledge in practice. For example, the choice of the best anesthetic agent for a given case rests on a foundation of science, the administration of the agent chosen, largely on skill or art. Increased knowledge and experience, together with skill in the use of anesthetics and allied drugs has made the anesthetist more useful to his associates the surgeon, the obstetrician, the internist and the diagnostician, and so he becomes of increasing value to institutions that wish to develop an organization in anesthesia and associated fields. The attitude of many surgeons in encouraging anesthetists has been a great aid to progress in the field.

One of the most striking advances in respect to anesthesia with gas is the refined equipment made by manufacturers of gas machines. They have kept pace with the changing demands as new anesthetic agents and time introduced new technics. They have cooperated with anesthetists in carrying out their ideas. The first of modern gas machines was made in 1923 by Foregger with a separate control each for nitrous oxide, ethylene oxygen, carbon dioxide and ether.[18] Further contribution in a mechanical way has been the development by Waters[19] of the use of the soda-lime absorber in connection with gas anesthesia. This has reduced the cost of the administration of gases or other anesthetics by inhalation to the lowest practical level.

In nonsurgical cases there are the advantages of the new Drinker machine for artificial respiration and patients with surgical conditions now have available to them a new type of apparatus on which I have been working for ten years.[20] This apparatus can be used in connection with the intratracheal tube, and sometimes an inflatable vest can be employed.

The manufacturing chemist, although he, like the rest of us, is in business to make a living, should also, like the rest of us, be given his share of credit for the development of new substances that allay or abolish pain, and for establishing and maintaining a high standard of quality of his products. It seems to me that particularly worthy of praise are those manufacturers who having developed a new product which they have every reason to believe is beneficial and innocuous, delay putting the product on the market until experienced physicians, in actual practice, have been able, by means which are safe for patients, to confirm the findings of the manufacturers.

Opportunities for anesthetists are greater now than before. From the standpoint of economics the field of anesthesia is less crowded by members of this association than most other fields and, although more physicians than formerly have been studying anesthesia, this field offers many opportunities, especially for younger men. I think that it would be to the advantage of this association and its members to encourage especially some of the men who have just finished internships to devote their time to this subject. There are opportunities now for such study; previously no courses were offered. Publications dealing with anesthesia and related subjects have augmented the educational opportunities of this specialty. There are now three journals on anesthesia, one published in Germany, one in England and one in the United States. Societies of anesthetists are meeting regularly, and in a short time anesthesiology will be a regular specialty. I hope that this organization will soon recognize it.

ABSTRACT OF DISCUSSION

ON PAPERS OF DR LAHEY, DRS SEEVERS AND WATERS AND DR LUNDY

Dr J T Halsey, New Orleans: In the discussion by Drs Seevers and Waters of the effects of paralysis of the intercostal muscles on the circulation during spinal anesthesia, it seemed to me that perhaps the authors did not emphasize sufficiently the bad effects on the circulation of the failure of the normal respiratory sucking and pressing in the chest which is responsible to so great a degree for keeping up the supply of blood to the heart. I thought that I could read in some of the charts a justification for my conviction that the interference with this mechanical factor is a grave thing. It seemed to me that these charts made it clearly evident that artificial respiration by the means of the Drinker apparatus was much more efficacious in restoring and maintaining the blood pressure than was the mere supplying of an extra concentration of oxygen to the patient. The mechanical difficulties connected with the application of that kind of artificial respiration to a surgical patient in the amphitheater are great, I am sure. I was consequently interested in what I took to be an intimation from Dr Lundy that he is on the way to getting something in the nature of a Drinker apparatus that can be applied only to the chest and so can serve as a really efficient physiologic method of improving the circulatory function in these patients. I should like to emphasize the importance of adopting all means possible to avoid the very rare but usually disastrous ethylene explosions. If I understand the views of Drs Seevers and Waters and what, it seems to me, they have proved about the state of affairs of the circulation in these high spinal anesthesias, a dilatation of vessels occurs in the splanchnic area, which those authors, in common with others, do not consider very important; there is a dilatation of the vessels and a change in regard to the physical conditions in the voluntary muscles through the body which make difficulties for the proper circulation of the blood, and the anoxemia leads to an impaired cardiac output. As a result of what I think is known about the action of ephedrine on cardiac output in some other conditions, I believe we ought to reserve our judgment and be cautious as to how we use it in these patients. Physicians should not feel that ephedrine is so surely a life saver that they can permit themselves to be careless.

DR. E. STARR JUDD, Rochester, Minn.: When I was on the Council on Scientific Assembly, it was constantly put up to us that anesthetists should be given a special section where they could work out their own problems. I opposed this, and I rather think Dr. Lahey opposed it, because we felt that anesthesia is a vital problem to so many different sections that the matters should be presented one year in one section, another year in another section. From my own experience, I think that although there are complications following the use of ether, and that ether is not entirely satisfactory, it is the safest anesthetic at the present time. Shortly after the war, a Parisian expert in administration of spinal and regional anesthesia was invited to the clinic, and we became greatly interested. We had some highly satisfactory experiences, and it looked for a time as though we were going to adopt spinal anesthesia pretty generally. However, after we had made a study of it, we concluded that, in our hands, spinal anesthesia and regional anesthesia were not as safe as ether. Then Dr. Lundy came to us, and since then we have been working constantly to try to find something that will improve spinal anesthesia, for nothing gives such satisfactory relaxation. I think I have saved some lives by using spinal anesthesia in very difficult reconstructions of the common bile duct. I have been enabled to do a much more accurate operation. So I like spinal anesthesia very much and I wish I could use it as much as I formerly thought I could. We had a woman patient with arthritis, cholecystitis and stones. Her general condition was not good, and we used spinal anesthesia. She had a smooth anesthesia, and an uneventful afternoon and night. The next morning, the blood pressure kept dropping. We supported her, but she did not improve, and died in two or three days. Necropsy revealed no cause of death. I don't know whether the spinal anesthetic was a factor, but I have always thought that if we had given the woman gas and ether she might have lived. In a period of ten years I had another similar experience. Finally, I gave up spinal anesthesia for abdominal work, much as I disliked to do so. It is the late effects, not the immediate effects, that have made us give up spinal anesthesia for abdominal surgery. If we can find either some drug or some instrument that will allow the same relaxation and ease of operation as we could obtain with spinal anesthesia, we shall have accomplished a great deal.

DR. A. M. CAINE, New Orleans: We are not troubled in this city with the anesthetic problem of the referring physician, but we are faced with the hospital technician whose one excuse for existence, from the hospital point of view, is that money may be made for the institution. The money thus made by the institutions employing technicians, thoughtlessly employed by the surgeon, seems to be a favorite theme at meetings of superintendents of hospitals. The practice is a hindrance to advancement in anesthesia, driving our best young men from engaging in the specialty. In his remarks on evaluation, Dr. Lahey has emphasized a most important point. Personal examination and follow up are most desirable; in fact, they are essential, for enthusiasm on the part of the anesthetist. We as anesthetists want to thank our friends who do so many patient hours of research work to prove or disprove a theory. They are our right hand in research.

DR. H. M. TRUSLER, Indianapolis: As a surgeon I am unwilling to tolerate any routine practice of anesthesia. I am especially unwilling to adopt the routine use of any agent that subjects the patient to the hazard of circulatory collapse or anoxemia. Certainly I regard spinal anesthesia as unsafe for routine use. It is difficult to obtain reliable statistics of anesthesia deaths, but it is probably true that the death rate due immediately to spinal anesthesia is close to 1 per cent. High spinal anesthesia I regard as especially dangerous because of paralysis of the thoracic muscles. It has always seemed to me that this factor greatly increases the hazard of circulatory collapse. From the standpoint of greatest safety under all conditions, if I were forced to rely on just one anesthetic agent, it would have to be ether. Since this is true I prefer to offset the objectionable features of ether by attempting to carry out what Dr. Lundy calls balanced anesthesia, using a combination of drugs in a way which I think will react best for the patient. In this effort I have especially enjoyed the use of the barbituric acid derivatives, and especially sodium amytal. When this drug is used in the proper fashion to produce a partial narcosis, I have found it a most valuable adjunct to anesthesia.

DR. M. H. SEEVERS, Madison, Wis.: In answer to Dr. Halsey, the reason I didn't mention more concerning the sucking and pressing action of the Drinker machine was the realization of the fact that the effect of the normal respiratory variations in intrathoracic pressure on blood movement is still controversial. Dr. Eyster recently has presented a paper indicating that under ordinary conditions the aspiring action of the thorax is of less importance than has been generally considered. We do not know what occurs under the abnormal situation existing in spinal anesthesia. The positive and negative pressures exerted over the whole body with the Drinker machine probably aid in the mechanical movement of blood. As far as the use of ephedrine is concerned, I think it has been fairly well demonstrated that small doses increase cardiac output. Chen and Meek were able to demonstrate this increase. If the dosage is large, the output is diminished. Our own results, both in the laboratory and in the clinic, have been obtained with doses that will maintain the original blood pressure. Our results have been good provided the tissues are adequately oxygenated. Ephedrine depresses the conduction bundle, and if the heart is anoxic, as the result of diminished circulation of blood, it may act only as a cardiac depressant.

DR. JOHN S. LUNDY, Rochester, Minn.: With regard to the increased output of the heart with ephedrine, in our experiments, in which the blood pressure was reduced tremendously and then elevated with ephedrine given intravenously, there was a marked increase in the pulse pressure for a period of about thirty minutes. This effect in increased pulse pressure could be terminated immediately by section of the vagi or could be stopped by the administration of a large dose of atropine. I simply wish to add this observation since the question has been raised about the output of the heart in connection with the use of ephedrine. With reference to Dr. Judd's remarks concerning delayed untoward results of spinal anesthesia, I am afraid he may be right. I can produce under certain circumstances, without exception, permanent cord changes from the use of solutions of procaine hydrochloride given intraspinally, and the picture that is seen through the microscope checks closely with that of the paralysis which is seen in observing an experimental animal; the animal dies invariably from four to ten days afterward. The point is not proved, I appreciate that, but it will be recalled that for many years the controversy raged—were there or were there not delayed untoward results from the use of chloroform? Finally it was decided that there were. I am afraid we are going to go through the same cycle with regard to spinal anesthetics.

Origin of the Name Syphilis.—Fracastorius was not only a physician, poet, mathematician, physicist, and astronomer, but also a geologist who saw fossil remains as the bodies of prehistoric plants. He died in 1553 of apoplexy. In 1559 a statue was erected in his memory at Verona with a eulogy of the author of "that divine Poem Syphilis." This poem, written, as he says, in his lighter moments, brought him more fame than all of his scientific writings. It appeared first in 1530 and was dedicated to the illustrious Cardinal Bembo, his old friend and classmate at Padua. The following selection from the third book relates the legend of the shepherd Syphilis, who, for an act of impiety, was struck with the French disease. This poem became so famous that the word syphilis soon became the universal term for this disease and displaced all other designations. —Major, R. H.: Classic Descriptions of Disease, Springfield, Ill., Charles C. Thomas, 1932, page 37.

INDUSTRIAL DERMATOSES

WITH SPECIAL REFERENCE TO ALLERGY AND MYCOTIC DERMATITIS

EARL D. OSBORNE, M.D.
AND
EDWIN D PUTNAM, M D.
BUFFALO

Within the past few years research work and clinical investigation have entirely changed certain aspects of industrial dermatoses We refer particularly to the work of Jadassohn,[1] Bloch[2] and his co-workers, Sulzberger and Wise,[3] and Sulzberger[4] in the demonstration of the fundamental importance of allergy in the production of dermatitis or eczema, particularly by the employment of the patch test and the passive transfer method of Prausnitz and Kustner in their investigations. Alderson[5] has called attention to the dilemma in which the Industrial Accident Commission of California was placed in considering a case of sensitization to turpentine and paint. The questions asked of Alderson and his committee by the Industrial Accident Commission illustrate the necessity for a clarification of our ideas on this subject. This refers to general physicians, industrial physicians and, particularly, to dermatologists who may be called in consultation The second aspect of industrial dermatoses to which we wish to call attention is that of mycotic dermatitis.

ALLERGY AS RELATED TO INDUSTRIAL DERMATITIS

There should be a clear understanding of just what is meant by the term "allergy." We believe that Bloch's definition is the best at the present time, namely:

> Allergy is that state which has as its basis the property of certain groups of cells (organs) of the living organism to react in a specific manner when brought in contact with a substance, which is, as far as is known, foreign to the organ or cells the characteristic of this specific pathologic process lies in the fact that it is caused by the reaction of this exogenous substance with its specific cellular fixed anti-body The basis and the essence of allergy is the ability of the living cell to react with the production of specific anti-bodies to the stimulus of foreign substances which are therefore called antigens

The term idiosyncrasy so frequently heard is one which in the light of recent experimental work loses much of its former meaning. Idiosyncrasy used medically means a peculiarity of constitution, and a person who reacts to poison ivy is said to be idiosyncratic In view of the fact that it has been shown experimentally that 80 per cent of all persons are allergic to Ascaris,[2] 60 per cent to poison ivy,[6] and 45 per cent to orthoform,[7] and that by using a concentrated extract of primula Bloch[2] was able to produce an allergic state in the skin of 100 per cent of persons, the question arises, Where does idiosyncrasy end? If 60 per cent of people react to poison ivy, certainly it cannot be said that they exhibit a peculiarity of constitution and that the 40 per cent of persons are normal. It is our firm opinion that the term idiosyncrasy signifies little and leads to confusion. We also agree with Highman[8] that the designation "allergic dermatitis" should not be used. The person, and not the dermatitis, is allergic.

For the sake of brevity we list the following facts, which have been shown by experimental and clinical investigation to be of importance in the consideration of industrial dermatitis due to allergy:

1. Allergy can be brought about by substances of a nonprotein as well as of a protein nature.
2. The location of the allergy may be in a circumscribed area of the skin, such as the dorsa of the hands or forearms, or it may be present in the entire cutaneous surface or in all the organs and tissues in the human body. In industrial cases it is well to remember that the allergic area may be localized to certain parts, particularly to the hands and forearms.
3. The eczema tests of Jadassohn and Bloch, or, as they are called in this country, "patch tests," are superior to all others in the demonstration of a cutaneous allergy.
4. Stauffer[9] has shown that substances with a high hydrogen ion concentration produce a greater reaction than those with a neutral reaction. This observation may be of great future importance.
5. Bloch and Steiner-Wourlisch[10] demonstrated in their experimental work in producing sensitization to primrose extract in guinea-pigs that there was a so-called "incubation period" of from seven to ten days between the first application of the primrose extract and the appearance of an allergic reaction when tested. Percival,[11] in his work on paraphenylendiamine called this the "latent period." We believe "latent" to be a better term than "incubation."
6 Bloch and also Stauffer have been unable to demonstrate antibodies in the blood serum of patients with eczematous eruptions due to allergy by the method of Prausnitz and Kustner. Bloch emphasizes this fact as differentiating eczematous manifestations of allergy from hay fever, asthma, urticaria and eruptions due to drugs. He suggests the possibility that the antibodies are fixed in the cutaneous cells and do not become free in the blood stream. This point is of extreme importance in the consideration of therapy and further research, and may explain the refractoriness to desensitization of dermatitis due to allergy. Yet, Ramirez and Eller,[12] in 1930, reported three cases of dermatitis due to ragweed, four to silk, one to cat hair, four to horse hair and one to paraphenylendiamine in which they successfully produced a passive transfer. They did not state whether the reaction of the passive transfer test was of an urticarial or an eczematous nature, but, suffice it to say that, so far as we can discover and according to Bloch, no cases of positive passive transfer of an eczematous nature occur in patients with a dermatitis due to exogenous substances
7 Although specific antibodies have not been demonstrated in the blood serum of a patient suffering from a dermatitis due to allergy, it has been demonstrated many times that this allergy is specific for the particu-

lar substance or chemical, and that other substances or chemicals unrelated to the particular one causing the dermatitis will not produce a like reaction unless the individual is also specifically allergic to those substances or chemicals. This fact is of the utmost importance in industrial dermatoses. A dermatitis due to sensitivity to turpentine developed in a workman while working in a paint shop. He was forced to seek employment elsewhere when he recovered from the original dermatitis. He found work as a carpenter, and in a few days a new attack of dermatitis exactly similar to the original one developed. This second attack of dermatitis was said to be due to the fact that the first attack of dermatitis sensitized the skin to many different irritants. As a matter of fact, investigation showed that while the man was working as a carpenter he handled wood products on which turpentine had been used, and that he reacted violently to a patch test of turpentine.

In our study of industrial dermatoses due to allergy, we have reviewed two hundred and sixteen cases seen during the past five years, which corresponds to the period during which we have been performing patch tests as a routine in every case possible. For brevity we have grouped these cases, in order to bring out the particular points that we wish to stress.

GROUP I (One Hundred and Four Cases).—In the spring of 1931, a large rayon plant suddenly decided to change the composition of an oil used in the winding department from a nonsulphonated oil to a new sulphonated oil. About two hundred workers were employed on these winding machines, and their hands were constantly bathed in the oil. Nothing happened for three days, when a young woman reported a mild dermatitis of the face, neck, hands and arms. These cases rapidly multiplied during the succeeding ten days, until at the end of two weeks this dermatitis had developed in one hundred and four workers. Careful investigation of these cases showed the following facts:

1. All workers were exposed simultaneously.
2. The latent period varied from three to fourteen days, when the experiment ceased.
3. As new cases were appearing every day, it appeared probable that a much larger number of workers would have become sensitized to the oil.
4. Patch tests were strongly positive in all persons showing the dermatitis.
5. Two workers presenting normal skins were tested daily up to the time the dermatitis developed. The patch test became positive simultaneously with the appearance of the dermatitis on the exposed parts.
6. Three of these workers tested with ultraviolet light showed a markedly increased sensitivity.
7. Since this company has resumed the use of the oil formerly used, there have been no further cases of the aforementioned type.

GROUP II (Fifteen Cases).—In the summer of 1931, within a period of four weeks, in 15 linemen working for the Niagara Hudson Corporation on the high tension lines dermatitis of the hands and wrists developed, which varied from a mild erythema to severe bullous dermatitis with extension to the face and neck. Through the courtesy of Dr. H. J. Constantine of the Niagara Hudson Corporation, we were able to study five of these cases carefully, as well as to make tests in a number of linemen who did not develop the dermatitis. It was found that the cause was a new brand of rubber gloves which the linemen always wore while working on the high voltage lines. Investigation of these cases showed the following points of interest:

1. The dermatitis did not develop until after the new gloves had been worn for several days. The gloves were worn for a varying period each day, that is, from one hour to all day, in other words, there was a definite latent period.
2. Patch tests, with both old and new gloves, on linemen in whom dermatitis had not developed were negative. Patch tests with rubber removed from the new rubber gloves were uniformly positive in all five patients with the dermatitis.
3. Through cooperation by the company producing the gloves, it was finally demonstrated that the sensitivity was due to tetramethyl-thiuram-disulphide.
4. By changing the brand of rubber gloves, only a single lineman continued to have trouble. He had evidently become so sensitized that he reacted to the smaller quantity of the sulphur compound present in gloves which he had formerly used with immunity.

GROUP III (Eleven Cases).—These patients were florists; 10 of them were found to be sensitive to chrysanthemums or pompoms, both of which they had handled many times previously. The other case was found to be due to sensitivity to tulips. This patient had handled tulips for many years before showing signs of dermatitis.

GROUP IV (Twenty-Six Cases).—In 1927, a large aniline company suffered a severe explosion in one of its buildings devoted to the production of key materials such as nitrosophenol. Approximately 110 pipe fitters were employed to rush repairs to this building. Nothing happened for four days, and then one pipe fitter after another appeared with a severe dermatitis of the face, neck, hands and arms, which investigation showed to be due to contact with the chemical dust that had collected for years on the many pipes in the building. In these cases a definite period of latency was demonstrated.

GROUP V (Eight Cases).—These patients worked in a chrome-plating establishment. A change was made in the apparatus used, and the men were exposed to cyanide fumes. There was no trouble for three days, when five men complained of a mild dermatitis on the face, neck, hands and arms. In this instance again a definite period of latency was demonstrated.

GROUP VI (miscellaneous group: Thirty-Nine Cases).—In this group there were patients from many different industrial plants in and around Buffalo. There were four patients showing a positive patch test to paranitrosodimethylaniline, a chemical used as an accelerator in the curing of rubber, two patients from a rubber company with positive patch tests for sulphur powder, four patients from a chemical plant who gave positive reactions to nitrosophenol, and three other patients from the same plant, with positive tests for dinitrochlorbenzol. Other cases consisted of sensitivity to "flytox," varnoline, mineral spirits, kerosene, benzene, turpentine, acetone, xylene, crude coal tar, potassium cyanide, formaldehyde, thymolac, laundry chemicals, cleaning chemicals, soap, podophyllin, flour dust, duco and procaine hydrochloride. The remaining patients in this group were not tested, owing to a lack of cooperation either on the part of the company employing the patient or on the part of the patient himself.

At this point it is well to mention the fact that it is not always the fault of the physician that the cause of the dermatitis is left undiscovered. All too frequently the executives of the plant are unwilling to allow a careful investigation by the dermatologist to discover the exact cause of the dermatitis. Frequently the employee is taken back to work after the dermatitis has subsided and within a short space of time is discharged, because the company feels that there is too great a risk of paying further compensation by keeping the man around the plant. This is not generally true in our experience with the large companies. With the newer knowledge heretofore mentioned, it is distinctly up to the industrial physician and the consulting dermatologist to educate the executives of industrial plants regarding the great importance, not only to the company, but to the employees, of ascertaining the exact cause of the dermatitis. We can recall, in our experience, a considerable number of workmen who have drawn compensation for months and even years after having left the employ of the original plant in which the dermatitis first developed.

The technic of the patch test has been well described by others and need not be gone into here. The work of Stauffer[9] in Bloch's clinic is classic. In forty-eight of forty-nine industrial cases he was able to find the exact cause. We have been unable to match this percentage, owing at times to our own carelessness but usually to a lack of cooperation on the part of the industry or the patient. Industrial commissions and insurance companies should be acquainted with the advisability of determining the exact cause of any industrial dermatitis by means of the patch test.

The questions of compensation and permanency of disablement always enter into consideration. The cases divide themselves into the following groups so far as compensation is concerned:

1. Cases of mild dermatitis in which the cause is readily discovered, result either in no loss of time or a loss of time less than the law requires as a minimum for compensation. In New York State this is seven days. Such cases occasion no trouble.

2. Cases of a severe grade of dermatitis in which the cause is discovered and preventive methods are successful. These cases also present no difficulty from the angle of compensation.

3. Cases of moderate or severe dermatitis in which the cause is not found and the patient is discharged soon after he resumes work. These cases are too numerous and are usually a reflection on the sincerity of the industrial company.

4. Cases of severe or moderate dermatitis occurring in employees who may have worked for many years in responsible positions. Allergy has developed suddenly for which nothing can be done, in spite of the fact that the employee is a valuable man to the company. Usually such men are eventually forced to resign or are discharged, and must seek work elsewhere at greatly reduced salaries. These are sad cases and always occasion a sharp contest in the industrial court. In our opinion, such workmen are entitled to a certain amount of permanent disability compensation. From the facts cited heretofore in the literature and from our own experience as detailed in such persons, sensitivity develops from repeated contact with the particular antigens in question. If we were to answer the questions submitted to Alderson[5] and his committee regarding a case coming under this category, we would be forced to answer the questions as follows:

1. The first attack of dermatitis was caused by repeated previous exposures to the particular antigen.

2. There is a great deal of evidence to show that over 50 per cent of persons will react to a given antigen if repeatedly exposed to it.

3. Susceptibility to allergy is increased by repeated exposure.

4. Our impression is that in young persons with relatively thin horny layers allergy develops more rapidly than in an older person, other conditions being equal.

5. Susceptibility to allery is increased at a greater rate by repeated exposure than by age.

6. There is no positive experimental evidence that repeated attacks of dermatitis increase the susceptibility to allergy.

Regarding the cure of patients with allergic dermatitis, we have been unable to effect a cure in any case by any means at our disposal, including the intracutaneous and subcutaneous injections of gradually ascending doses of the particular chemical in question. We have observed a gradual lessening in sensitivity from lapse of time alone in a few cases that we were able to follow. We believe that the absence of free antibodies in the blood serum is the explanation of the refractoriness of these patients to treatment by desensitization.

MYCOTIC DERMATITIS IN INDUSTRY

So much has been written in recent years on eczematoid ringworm, fungus dermatitis, epidermophytosis or mycotic dermatitis, whichever term happens to be used, that physicians in general and industrial commissions are becoming well aware of this form of eczema or dermatitis. It has seemed to us that the diagnosis of a mycotic dermatitis has at times been made without sufficient evidence. As has been pointed out repeatedly by such men as Pusey[13] and Bloch, there is no difference pathologically between a mycotic dermatitis and a dermatitis due to some external irritant. Furthermore, it is frequently impossible to distinguish these two types of dermatitis clinically. We believe that before a diagnosis of mycotic dermatitis is made, the following points should be considered:

(1) A history of preexisting dermatitis in areas characteristically involved by superficial invading fungi, such as the toes, the groin and the interdigital spaces of the fingers. Referring to the latter, we have been misled several times by the appearance of vesicles in the interdigital space between the first and second fingers of the left hand of dentists. A diagnosis of dermatitis due to procaine hydrochloride should seldom be made unless proved by a patch test.

(2) Clinical evidence of preexisting chronic foci of fungus infections. Too frequently, the toes, groins and perianal regions are left unexamined when a persistent dermatitis on the hands is being considered. Repeatedly we have found an active vesicular ringworm infection of the feet in patients with a supposed industrial dermatitis of the hands.

(3) Smears and cultures, when positive, are of marked assistance. In approximately one half of the cases of known mycotic infection, such examinations are negative. We believe that a careful clinical history and examination are generally of more value than smears and cultures. A period of observation of from two to four weeks is extremely valuable in many instances in making a definite diagnosis of mycotic infection.

(4) We have frequently found that it is necessary to rule out the question of a dermatitis due to allergy by

---

[13] Pusey, W. A.: The Principles and Practice of Dermatology, New York, D. Appleton and Company, 1924.

various patch tests before arriving at a diagnosis of mycotic dermatitis. In going through our records, we found that thirty-two patients of a total of one hundred and seventy-five showing evidence of mycotic infection presented, in addition, a dermatitis due to allergy to some particular chemical. Frequently, an industrial dermatitis superimposed on a chronic mycotic infection of focal areas produced a marked flare-up in the mycotic dermatitis. The following case is an excellent example:

A worker in an aniline company suffered a severe attack of dermatitis due to allergy to dinitrochlorbenzene. He recovered from this dermatitis in about three weeks, chronic areas involving the palms, groins and feet persisting. This dermatitis caused him to receive compensation for about eight months, during which time and for periods of several weeks, he was many miles distant from the plant. Examination of him at this time revealed a characteristic mycotic infection of the areas previously mentioned, with positive smears and cultures. The dermatitis was properly treated, and in a few weeks he returned to work. A severe exacerbation of the dermatitis on the hands, including the palms, dorsal surfaces and forearms, developed. Patch tests showed him to be extremely sensitive to dinitrochlorbenzene.

(5) Every industrial physician and dermatologist should investigate each case of so-called eczema of the hands occurring in an industrial plant with which he is connected. We have had a number of interesting experiences along this line. In one instance, it was found that six cases of ringworm of the hands in chemists, all handling the same reagent bottles, developed from contact with another chemist with a chronic recurring eczema of the hands.

Because of its increasing prevalence, the question of whether a given case of mycotic infection is compensatable is receiving more and more attention in our industrial courts. We have found that the most exacting examination and history as previously outlined is necessary in order to answer the questions propounded in the industrial courts. We believe that mycotic dermatitis is compensatable:

1. When the source of infection can be proved to be a contact in the same plant, as in the case of the chemists previously mentioned.
2. When an industrial dermatitis or injury predisposes to the exacerbation and spread of a chronic mycotic infection. This comes under the category of aggravation, a subject that is so common in industrial courts at the present time. The compensation should end when the primary acute dermatitis has subsided and only the chronic foci remain.

We believe that a chronic, recurring mycotic dermatitis, aggravated by heat and moisture, should not be compensatable, because these factors are common to all industry. Seventy-five per cent of the cases of mycotic dermatitis in industry fall in this category, and usually a claim for compensation is made by the person so affected. It behooves every industrial physician and dermatologist to investigate such cases thoroughly and to establish a diagnosis beyond doubt. We emphasize again that, from clinical inspection alone, it is sometimes impossible to differentiate a mycotic infection from an industrial dermatitis due to chemicals. In times of economic depression and resulting unemployment, the presence of a mycotic dermatitis of the hands is a ready excuse for claiming compensation. With the widespread prevalence of this infection among the general population, it is not at all strange that many cases should appear among workingmen.

COMMENT

In this paper we have attempted to cover the two most important phases of industrial dermatoses, namely, dermatitis due to allergy and mycotic infection. Ninety per cent of industrial dermatoses fall in these two categories. The advance in our knowledge in the past few years has been sufficient to change greatly our concept of these two phases of industrial dermatitis. There have been many controversial problems that can be definitely settled.

The era of immediate or snapshot diagnosis in any case of industrial dermatitis has definitely passed. To examine a patient properly and to diagnose a case requires a great deal of time, patience and a certain amount of inquisitiveness and detective ability, as well as the proper laboratory facilities. Large collections of substances used in industry must be kept on hand for patch testing. Proper laboratory facilities must be available for mycotic studies. In our opinion, the time and energy spent in determining the exact cause of a given case is well worth while. In fact, from the standpoint of the dermatologist, nothing is more satisfying than the solving of a group of difficult cases of industrial dermatitis.

Lastly, the economic side of industrial dermatitis due to allergy and mycotic infection is of vast importance. It is apparent to any one familiar with industrial court cases that large sums of money could be saved by industry if a prompt diagnosis, backed by a scientific proof, were made, and the proper preventive measures were instituted. In the long run, it is the employee who benefits the most. No honest workman desires to live on compensation and be deprived of his full earning capacity, not to mention the weeks and months of suffering due to dermatitis. If a change in occupation is found necessary, the sooner it is accomplished the better for all concerned.

ABSTRACT OF DISCUSSION

Dr. C. Guy Lane, Boston: I subscribe to the authors' statement with regard to the localization of sensitization in the cutaneous cells. I remember well the first case of procaine hydrochloride dermatitis I saw in which the skin tests were positive on the patient's arms and negative on the body, lips and mucous membranes. Later tests on the arms at the sites of the previous tests gave stronger reactions than the early tests. I also agree that the patch tests are the best method available at present. I was interested to hear of the positive skin tests at the time of the onset of the dermatitis. The latent period, I think, is of extreme importance, for one has to go a little further back in the histories to get the pertinent facts in individual cases. In regard to specific sensitization, it has been my belief for some time that one attack of dermatitis has lowered the skin resistance to other types of irritation. Perhaps I shall be a little less sure of this after hearing the amount of evidence the authors have brought up regarding specific sensitization. At the same time, I am reminded of the work of Gardiner, in Edinburgh, who reviewed his cases of industrial dermatitis and found two predisposing factors which were important: first, the history of a preceding dermatitis, and, second, a recent intercurrent illness seemed definite predisposing factors in his group. I have not felt that these factors were as large in the group I have seen, but I have felt that they have played a part. I am glad that the advisability of disability in connection with skin cases was emphasized. I think many industrial firms and some insurance companies fail to recognize that disability can be produced in the skin in the same way that it can be in eye and bone injuries sustained in industry. I also believe that repeated attacks of an industrial dermatosis definitely increase the sensitization of the in vidual and therefore increase the total disability. I have f that "dermatophytosis" is a little better term than "myc dermatitis" because these cases, if they are proved cases, will need to be classified as infectious skin disease rather than as a dermatitis or eczema. The cases that I have seen with regard to compensation because of a fungous infection I have attempted to classify in five groups: (1) primary cases, which are unusual in industry; (2) cases in which industry contributes to the exaggeration of a fungous infection and increases the disability; (3) cases which start as true industrial dermatoses and then are complicated with a fungous infection; (4) cases in which the patients are sensitized by a fungous infection, though I am not absolutely sure this group exists, and (5) cases in which there is no relationship

Dr. Harry E. Alderson, San Francisco: This paper covers some phases of a subject that is becoming increasingly important, with the growth of health and accident insurance and the rapid spread of a disease that might be called "compensationitis." A high percentage of alleged occupational dermatoses may be mycotic infections or other dermatoses, not necessarily industrial. The certainty that many cases originate at home or away from the job, or that they are at least aggravated by outside factors, complicates the situation It would pay executives to have home investigations made in many cases I have been skeptical about turpentine sensitization, believing that it existed but that many reported examples were not truly allergic. This applies also to many other nonprotein substances that in themselves are essentially irritating or cauterizing in their action Since publishing my paper, I have heard of many cases. My report was more or less in the nature of a challenge and a call for help, and I am pleased with the response One must be on guard, however, in using patch tests with substances that are in themselves usually irritating, particularly when the suspected material is covered with an impermeable substance such as rubber It even applies when solutions are merely sprayed or rubbed into the skin The relationship of mycotic infections to industry is important, and here knowledge of the patient's home environment and habits is of particular value Irritating substances to which one with a nonindustrial mycotic dermatosis is exposed will often render the condition acute and more or less disabling Naturally, such cases for the time being are industrial I have had many such cases. Two women with chronic, dry, mycotic infection of several finger nails were referred to me by the California State Compensation Insurance Fund. Their nail troubles were of several years' standing Their work exposed their hands to sugar solutions for several hours daily. One patient presented also an acute paronychia around several nails My ruling that only the latter case was to be regarded as occupational and treated until the acute disabling inflammation subsided was accepted by the company. My recommendation that the other case be rejected was likewise accepted In my opinion there is no branch of practice that calls for greater training, experience and skill than is required of dermatologists in handling these cases. Perhaps some day the insurance carriers will realize this fact Some of them already have found that it really pays them to call in a specialist early.

Dr. Harry Foerster, Milwaukee The recognition of the existence of a latent period in the development of a dermatitis is important in compensation cases. A dermatitis venenata or an infectious eczematoid dermatitis may develop following the healing of an injury. The question that arises is, What relation does one bear to the other? The intact horny layer being a natural defense against chemical irritants and infections, a break in this defense as a result of a minor occupational injury may result in a major disability-producing dermatitis, and failure to recognize the existence of a latent period in the development of such a dermatitis may result in an erroneous interpretation of the question of liability In consideration of the prevalence of epidermophytosis, it is likely that many patients with occupational dermatoses of the hands may have previously had epidermophytosis infection or epidermophytid inflammation of the hands It is possible that such a condition, if proved to have shortly preceded the development of an occupational dermatitis, may be considered as having produced a local hypersusceptibility to the occupational disorder; also that a localized active epidermophytosis may cause a general hypersusceptibility to other types of inflammation and predispose to the development of an occupational dermatosis.

Dr. Jeffrey C. Michael, Houston, Texas: In Texas we have the same problem that Dr. Foerster mentioned, because we have no compensation for industrial dermatoses. However, we have the difficult question to answer whether the dermatitis that follows an injury is compensable as an accident. One of our problems is gasoline dermatitis. Gasoline is a primary irritant and there seems to be no satisfactory diluent. I have tried to work out a contact test for this substance which would be reliable. On myself as well as several other normal controls I have found that gasoline under an impermeable contact test produces an irritation after fifteen minutes' application Therefore with gasoline I am at present following the usual technic for contact tests but leaving this test on for only twelve minutes. I should like to know whether others have worked out a solution of this problem. With regard to the cases of mycotic dermatitis, in the transactions of the Copenhagen congress there is a discussion by Keller of Freiburg on the paper of Mattas in which it is stated that in the vesicular type of fungous infections those vesicles having an acid content never show fungi. During the past summer I tried this out in about sixty cases and found that Keller's statement was correct. My experience showed that the vesicles with alkaline contents might or might not show fungi Of course, these results ought to be corroborated, but it now seems fairly certain that a good deal of time can be saved by discarding the vesicles with acid contents and examining only those that are alkaline.

Dr. Lester Hollander, Pittsburgh: There are two points of information which I should like the authors to give. First, if the definition of allergy as stated by Doerr is correct, that it is a reaction different from the normal, occurring in a minority of individuals, is it not questionable whether dermatitis produced on this basis in industry is compensable or not? The specific substance that produced 104 cases of dermatitis in the series of Drs Osborne and Putnam cannot be classed as an allergy producer I would class it as a strong irritant, which undoubtedly would cause a dermatitis in most individuals and unquestionably should be compensable. The second point with regard to industrial dermatoses was brought up by Oppenheim of Vienna at the Copenhagen congress; namely, that not only specific substances but the manner in which certain work is performed is a factor in their production: for instance, the rolling motion of the hands in the bakers. I wonder whether the authors can throw light on this question

Dr Bedford Shelmire, Dallas, Texas: In a suit for compensation in a case of occupational dermatitis, the question arises as to whether the individual developed the sensitization from daily exposure to the exogenous substance in question or was already sensitive when he began the occupation If the sensitization developed from exposure to some substance encountered in his work, the injury is certainly compensable. Theoretically it appears that individuals do become sensitized by repeated exposure to irritants encountered in their work Practically this has not been the case in my hands, for attempts to sensitize individuals by repeated exposure to turpentine, gasoline and the like have met complete failure. On the other hand, I have easily sensitized individuals to poison ivy (radicans) It has been conclusively shown that specific hypersensitiveness to poison ivy develops only after previous contact with the plant It is a recorded fact that the Eskimos of Baffin-Land are not sensitive to the extract of the ivy plant. As the ivy plant does not grow north of the mouth of the St Lawrence river, these natives in Baffin-Land have never received a sensitizing exposure. The American Indians, who are believed to be closely related to the Eskimos, have been found by many observers to be as frequently subject to ivy sensitiveness as are the white people. New-born infants without exception have been found nonsensitive to ivy. When these infants were tested some weeks following the initial or sensitizing dose, they were found sensitive in about the same percentage as adults. From these observations one is inclined to believe that certain individuals become specifically sensitized to substances encountered in their work.

Dr N P Anderson, Los Angeles: One must be most cautious in expressing an opinion regarding compensability in many cases In the case of the workers in the rayon plant cited by the authors, where some 100 of the employees developed a dermatitis following the use of a new type of oil, I think that there can be no question as to the cause or the compensability. However, let us suppose that only one worker out of the 200 or more exposed developed a dermatitis and that he reacted positively to the patch test of the oil. We would still probably maintain the position that such a dermatitis was compensable. However, let us look at the other side of the question. The dermatologist uses ammoniated mercury a great deal. Suppose now, a patient to whom a 2 or 3 per cent ammoniated mercury ointment was prescribed develops a severe local dermatitis that can be proved to be due to the ammoniated mercury ointment; or let us go further and say he develops a generalized exfoliating dermatitis and requires hospitalization for a month or so. In such a case, and one that can happen to any one of us, do we hold ourselves responsible for the condition? Are we willing to pay the patient's hospital bill? If one of our stenographers develops a dermatitis due to carbon paper, should we be held responsible? If a severe and disabling eruption occurs after a hair dresser or beauty shop operator applies an aniline dye for cosmetic purposes, is the hair dresser to be held responsible for such a condition? I do not know the answers to these questions but feel that one should exercise great caution in expressing opinions. In a recent paper, as yet unpublished, the statement has been made that out of some 280 cases of suspected industrial dermatitis, less than 5 per cent of them were actually due to an industrial irritant. I believe this percentage is much too low and should like to ask the authors, In what proportion of all their industrial dermatoses did they prove the cause to be an irritant of occupational nature?

Dr. Fred D. Weidman, Philadelphia: The fact should not be overlooked that fungi can arrive on the patient's skin as the result of contact with raw materials used in industry. I bring the point up as a text to illustrate that it is necessary to have a complete perspective of the biology of fungi in epidermophytosis if one would be equitable to employee and employer alike. A slight knowledge of the habitat of dermatophytes in nature has been obtained. It has been shown that these organisms can not only exist but grow on such things as straw, hay, feathers and leather. Kingery has shown that a fungus of pears is associated with canner's dermatitis in the Northwest. In California, a monilia of oranges induces dermatitis in orange packers. In Formosa, an organism was present in the stalks of hibiscus, a plant which entered into the fabrication of flax and which induced a dermatitis. From a different angle, it is known that diabetes predisposes to certain fungous infections. Dogs with diabetes are susceptible to oidium infection, whereas nondiabetic dogs are not. A problem that came up in a Massachusetts case concerned a person who had both a turpentine dermatitis and a mycosis. The question was whether the mycosis was superimposed, and I understand that is an important point in law. This is a vital point, on which the dermatologist can be of great service. The point is the early examination of these patients to discover whether, *early in the course of the difficulty*, a fungus could be demonstrated.

Dr. Harold N. Cole, Cleveland: The time element must always be considered in connection with these cases. Many times it is difficult to decide whether it is an industrial condition or whether it is something these individuals are coming in contact with in their daily life. I will mention a couple of instances. A stenographer came to us with an eruption of the face and neck which came and went: It was apparently not from carbon paper, the Sunday newspaper or anything she was using on her skin. Finally she told us one day that the process appeared at the same time the young man she was engaged to had been to see her. On investigation we found that this young man was using a hair tonic on his scalp. We had him come in, made a patch test and applied it to the patient, and found that the eruption was due to resorcinol, which was in the hair tonic. The time element may come in and we may find many of these cases due to something in the patient's daily life. In the case of a man with an eruption over the face and hands, it might have been due to something connected with his business but we could find no explanation. He went to California and there everything disappeared, but when he returned to Cleveland everything started up again. Further investigation of his home conditions disclosed that he was coming in contact with the offending agent there in the form of orris root used on his wife's hair.

Dr. Everett S. Lain, Oklahoma City: Had any members of the dental profession been present today and heard these discussions, they would have been first amused and then edified. They have for a long time had under discussion rubber as a basic dental material cause for troubles in the mouth. They are of the opinion that there is a possibility of oral mucosa irritation caused by sulphide of mercury, which gives the rubber the red appearance; also sulphur, which is used for hardening. They have concluded that most of the trouble is due to lack of proper curing. Many dentists recommend that dental plates be immersed in soda water during the night. They have learned by experience that it keeps them in better condition. I have learned that this irritation is more likely to occur in a mouth that is excessively acid rather than alkaline.

Dr. Earl D. Osborne, Buffalo: I shall confine my remarks to a few of the questions which have been asked. It has been inferred, by a few of the speakers, that the cases at the rayon plant were examples of irritation and not of true allergy. I would point out again that these workmen had never been exposed to the oil before. Had it been an irritative dermatitis, some evidence of irritation would have been apparent within the first twenty-four hours. As a matter of fact, no case appeared until the third day, and new cases were appearing after two weeks' use of the oil. Furthermore, the individuals presenting the dermatitis showed a positive patch test coincident with the beginning of the dermatitis, whereas it was negative before. Various solutions of the oil were used in testing, that is, from 1 : 10,000 down to the full strength oil. In at least one individual who was highly sensitive, the test with a fraction of a drop of 1 : 1,000 dilution of the oil produced a terrific dermatitis. Any one who attempts this work must perfect himself in the technic of the patch test. Dr. Lane brought up several important questions. What is the influence of previous attacks of dermatitis on the development of allergy? Several factors are concerned in this question. A person who has had repeated attacks of dermatitis on the hands and arms from any cause certainly absorbs more chemical into the general system from these areas than a person who has had a normal skin on those areas. But one should keep one's conception of allergy clear and not place the blame for the subsequent dermatitis on the first dermatitis when there is a definite allergic factor which can be elicited by adequate testing. Furthermore, one must always remember group sensitization. For instance, turpentine is only one member of a group of chemicals derived from wood which may be in the same chemical group as a number of other substances derived from the same source. I believe that further observation will show that in every new case of dermatitis due to exogenous substances a latent period will be demonstrated. As to disability compensation, certainly some of these individuals falling in one of the groups mentioned are entitled to a certain percentage of permanent disability. I refer particularly to those who have worked for varying periods of time and suddenly become extremely sensitive to an industrial chemical which necessitates their removal from that particular industry. There is no satisfactory treatment for these cases and just how many of them will clear up in time it is impossible to say. In doing tests with gasoline, we always use just a fraction of a drop, that is, the amount which will adhere to the tip of a wooden applicator stick. This is applied to the center of a small piece of gauze and exposed to the air for about thirty seconds and then applied to the skin with a layer of rubber dam over the gauze. In the case of true allergy, there will be an eczematous reaction more extensive than that due to irritation. Dr. Foerster raised the question of a dermatitis due to allergy following local injuries or bruises. This is a difficult phase for investigation. In the first place, one is dealing with an area of localized tissue sensitivity. If looked for, a definite period of latency should be found between the time of first exposure and the development of the dermatitis. Usually one does not have these patients under observation long enough to test their sensitivity. As soon as the dermatitis disappears, they disappear. In regard to the question of Dr. Shelmire, about whether allergy is acquired or inherited, my opinion is based on my own experience and the literature and is that in practically all cases it is acquired. At least the burden of proof is on those who would prove a congenital allergy.

SIGNIFICANCE OF IMMUNITY TESTS IN EPIDEMIOLOGY AS ILLUSTRATED IN YELLOW FEVER

T. P. HUGHES, Ph.D.
AND
W. A. SAWYER, M.D.
NEW YORK

Immunity tests are taking an important place in epidemiologic studies of several diseases of man. In diphtheria, scarlet fever and tuberculosis skin tests are commonly used. In poliomyelitis and yellow fever the serum is tested in animals, in the former by a neutralization test and in the latter by a protection test. If a result indicating immunity is obtained by any of these procedures, it is assumed that the person tested has previously been infected with the corresponding causative agent. Such evidence of a preceding immunizing infection is so frequent in persons who give no history of an attack of the disease under investigation that a high prevalence of unrecognized and subclinical cases is commonly assumed. Another possible explanation would be that the immunity tests are not so specific or so reliable as has been believed.

The specificity of immunity reactions, particularly the Schick test in diphtheria, has been questioned by Friedberger, Bock and Furstenheim,[1] who showed that the serums of persons or animals may possess certain antibodies—or at least physiologic properties enabling the serums to act on antigens—in the absence of specific immunization. Moreover, such antibodies were found to vary quantitatively with the age of the persons supplying the serum. These observations were presented as evidence that immunity reactions commonly supposed to be due to previous specific infection may depend on nonspecific physiologic factors. In immunity tests for each of the diseases that we have mentioned, including yellow fever in regions in which the disease is endemic or intermittently epidemic, it has been observed that the frequency of the result indicating immunity has, in general, risen with age. This is what would be expected if the immunity tests revealed the cumulative experience of the community with specific infection, but the hypothesis that the reactions may be physiologic maturation phenomena requires careful consideration.

Experiences in which immunity reactions are being obtained in persons who have presumably not been exposed to the specific infectious agent continue to be reported. It was observed by Heinbecker and Irvine-Jones[2] and also by Bay-Schmith[3] that a large percentage of certain Eskimos living in regions in which diphtheria had not been recognized gave a negative Schick reaction. Wells and Heinbecker,[4] however, later found organisms morphologically resembling diphtheria bacilli in the throats of Eskimos.

It has been observed by a number of investigators that high proportions of the population give negative reactions to the Schick and Dick tests in tropical and subtropical regions in which clinical diphtheria and scarlet fever are rare. Doull, Ferreira and Parreiras,[5] for example, obtained such results in Rio de Janeiro, and Parr, Goodale and Krischner[6] did the same in Syria.

A widespread immunity to poliomyelitis, as evidenced by serum neutralization tests, in adults with no history of poliomyelitis has been reported by Aycock and Kramer[7] and others. Recently Soule and McKinley[8] found that the serums from eight residents of Porto Rico, where clinical poliomyelitis is rare, all had the power of neutralizing poliomyelitis virus. The possible existence of a nonspecific maturation factor in poliomyelitis immunity has recently been discussed by Jungeblut and Engle[9] and the suggestion made that the immunity may be due to a hormonal balance characteristic of adult life.

An obvious way to determine the specificity and accuracy of immunity tests would be to apply them to a considerable number of persons whose previous experience with the corresponding infections is definitely known. In diseases as widespread as diphtheria, scarlet fever, tuberculosis and poliomyelitis, it is impossible at present to rule out previous contact with the causative organism in any inhabited region. In yellow fever, on the other hand, there are large populations known beyond reasonable doubt not to have been exposed to yellow fever or its virus. The insect vector is absent in large areas of the world, and in other regions, in which the vector is found, the disease has not been present within historical time.

Under these favorable conditions we undertook to investigate the specificity and accuracy of the immunity test now being widely used in epidemiologic studies of yellow fever: the intraperitoneal protection test in mice, as described by Sawyer and Lloyd.[10] In this test 0.03 cc. of sterile 2 per cent starch solution is injected intracerebrally into each of six anesthetized mice to localize the virus in the brain. Immediately thereafter the mouse is given an intraperitoneal injection of a mixture of 0.2 cc. of a 10 per cent suspension of virus-containing mouse brain and 0.4 cc. of the serum to be tested. Control groups of mice are given injections in the same way, except that known normal and immune serums are substituted for the serum to be tested. Mice dying from five to ten days after inoculation are considered to have died of yellow fever encephalitis if the results with the control groups are satisfactory. At least five out of six mice must survive if the result is to be considered "protection," and likewise five out of six must succumb if the result is "no protection." Results falling outside these narrow limits are regarded as "inconclusive."

TESTS OF SERUMS FROM CHINA

The part of the world most definitely known to be free from yellow fever is the Orient. Through the courtesy of Dr. J. B. Grant, Dr. H. L. Amoss and Dr. I C Fang, of the Peiping Union Medical College, we obtained serums from eighty-eight Chinese residing in Peiping who had never been outside of China. In

tables 1 and 2 is given the classification of the donors of these serums by age, sex and race. These known "normal" serums from China were examined by the protection test in mice. Whenever the quantity of serum would permit, the test was repeated on another day. In no case was the result "protection." The results are shown in table 3.

TABLE 1.—*Distribution of Donors of Serums by Age Groups*

	Number of Persons in Each Series Tested				
Age Group	Chinese Group	Canadian Group A	Canadian Group B	American Negro Group	Panamanian Group
5 - 9	..	..	..	..	6
10 - 14	..	..	..	..	8
15 - 19	..	2	..	3	17

85 - 89	..	..	..	..	1
Unknown	1	..	..	..	..
All ages	88	51	58	20	96

In the application of this standardized yellow fever protection test to serums of Chinese who could never have been exposed to yellow fever, there were no false positive results and few inconclusive ones. No evidence of physiologic factors capable of giving yellow fever immunity reactions was obtained by this method, not even in fully matured persons. The ages of the donors ranged from 21 to 53, and it will be noticed in table 1 that forty-six, or more than half, of the persons supplying serum were over 40 years of age. There was no opportunity to test a group of persons of the same race after known attacks of yellow fever.

SERUMS FROM CANADA

Another region from which yellow fever is definitely absent is Canada. Through the kindness of Dr. J. G. FitzGerald and Dr. D. T. Fraser, of the School of Hygiene, University of Toronto, we secured serums from 109 residents of Canada. The donors of serum were classified in two groups: (*A*) fifty-one who had never been outside of Canada and (*B*) fifty-eight who had been in noninfected parts of other countries—Europe or the western, north-central or northeastern parts of the United States. Except on the western coast, none of the donors who had been in the United States had been farther south than Baltimore. The distribution of the donors by age, sex and race is shown in tables 1 and 2. The results of the tests in mice for protective power against yellow fever are given in table 3. The tests were repeated only when the results were "inconclusive" or "protection." In each group there was one serum giving "protection," but when the test was repeated the result was "inconclusive." It happened that the first tests of both these specimens were in a series in which virus was used which had been kept frozen overnight to economize virus, contrary to the usual method. Subsequent experience has shown that such treatment causes appreciable injury to the virus, and tends to increase the number of mice surviving in the test and thus heighten the risk of false positive results indicating protection. It seemed important, however, to investigate more closely the five serums which gave "inconclusive" results in both tests or "protection" followed by an "inconclusive" result. Two of these five serums were shown by additional tests to belong rightfully with the group showing "no protection." The first was in group A and came from a woman aged 21. The number of mice surviving was only three out of six and two out of five, respectively, in the first two tests, and was none out of five in each of three successive tests made with a new specimen of serum. The second of these serums was in group B and was from a man, aged 48. Only two mice out of six survived in each of the first two tests and one out of six in a third test.

TABLE 2.—*Race and Sex of Donors of Serums*

		Sex		Race or Color				
Serum Group	Total No. Donors	Male	Female	White	Chinese	Negro	Indian	Mestizo
Chinese........	88	78	9*	..	88	..	..	..
Canadian A....	51	33	18	51	..	..	..	..
Canadian B....	58	31	27	58	..	..	..	..
American Negro	20	15	5	..	..	20	..	..
Panamanian...	96	45	51	9	..	52	14	21

* Sex not specified in one case.

TABLE 3.—*Results of Tests and Retests of Chinese and Canadian Serums*

	First Test		Second Test			
Serum Groups	Result	Number of Serums	Number Giving No Protection	Number Giving Inconclusive Result	Number Giving Protection	Test Not Repeated
Chinese	No protection	79	66	6	0	7
	Inconclusive	9	5	3	0	1
	Protection	0	0	0	0	0
	Total	88	71	9	0	8
Canadian A	No protection	37	..	..	..	37
	Inconclusive	13	10	1	0	2
	Protection	1	0	1	0	0
	Total	51	10	2	0	39
Canadian B	No protection	45	..	..	..	45
	Inconclusive	12	10	2	0	0
	Protection	1	0	1	0	0
	Total	58	10	3	0	45

This leaves three serums in which a slight protective power was suspected. The particulars regarding the donors and the results of the successive protection tests are as follows:

1. Group A. Woman. Age 28. Mouse survival ratio: first specimen, 4/5, 2/6; second specimen, 3/5, 3/6, 2/6.
2. Group B. Woman. Age 22. Mouse survival ratio: first specimen, 3/6, 3/5, 4/6; second specimen, 1/6, 5/6, 5/6, 4/6.
3. Group B. Woman. Age 39. Mouse survival ratio: first specimen, 4/5, 2/6; second specimen, 0/6, 2/5, 1/6, 0/6.

The number of successive inconclusive results obtained with serum 1 suggests that it may have had slightly more protective power than the average normal serum, but that the one "positive" result was not representative and was due to the use of virus attenuated by freezing and storage overnight. In serum 3 the one positive result was also obviously a mistake due to the same deviation from the usual technic. Serum 2, on the other hand, is of special interest. Except for the high mortality in the mice used in the first test with the second specimen, which cannot be explained, the survival ratio ranged from 3/6 to 5/6 and showed definite protective power just under the amount capable of giving "protection" with regularity.

We have, therefore, 1 serum, among 109 Canadian serums, which seems to give the results "inconclusive" and "protection," because of some property in the serum itself.

SERUMS FROM PERSONS KNOWN TO HAVE BEEN INFECTED

With few exceptions the Canadian serums came from persons of British stock. The serum of a small number of persons of the same general stock, who had previously experienced known infections with yellow fever virus, had been tested in mice by Sawyer, Kitchen and Lloyd,[11] and their results are summarized in table 4. In the last column of the table is given the range of the titers of the serums when tested in serial dilutions by the intraperitoneal protection test in mice. It will be noticed that serums of all these twenty-one persons known to have been infected with virus from three weeks to thirty years before their serum was obtained gave definite "protection" even when diluted. The one serum with a low titer (1/4) was from a person infected thirty years before in Cuba in an experiment of the Army Yellow Fever Commission under Walter Reed.

Table 4.—*Results of Tests of Serums from Persons Recovered from Yellow Fever or Immunized by Vaccination*

Method of Immunization	Time Interval Since Immunization	Result of Tests			Range of Titers
		No Protection	Inconclusive	Protection	
Known attack of yellow fever	26 to 30 years	0	0	3	1/4 to 1/512
Accidental laboratory infections	13 to 31 months	0	0	6	1/128 to 1/512
Vaccination with yellow fever virus and immune serum	3 to 30 weeks	0	0	12	1/64 to 1/512
Total		0	0	21	

These results give evidence consistent with that obtained in numerous experiments in monkeys and illustrate the certainty with which protective power can be demonstrated in the serums of persons known to have been infected in recent years. The low titer obtained long after vaccination in one case suggests that the antibody content of the serum of a person who has recovered from yellow fever may fall with the lapse of time in some cases and perhaps reach a point at which the protective power of the serum is not demonstrable.

TESTS OF THE SERUMS OF AMERICAN NEGROES

As the protection test in mice is being used in extensive epidemiologic surveys in Africa, it was of interest to test a group of Negroes who had probably not been exposed to yellow fever virus. It is well known that full-blooded Negroes in Africa and elsewhere, although apparently susceptible to infection, are more resistant to the effects of the disease than are persons of European stock. Through the kindness of Dr. J. H. Janney, Health Officer of Anne Arundel County, Maryland, we received 20 serums from Negroes residing in or near Annapolis. That their ancestry was principally Negro was concluded from their skin color. All were born in America, but four had been farther south than Maryland or had visited in foreign countries.

The results of the protection tests were "no protection" in nineteen instances and "inconclusive" in one. None of the tests have as yet been repeated. There was no evidence of any protective power in these twenty serums.

SERUMS FROM PANAMA

Col. J. F. Siler, Chief Health Officer of the Canal Zone, and Dr. L. B. Bates, Chief of the Board of Health Laboratory at Ancon, were kind enough to send us ninety-six serums collected in the Republic of Panama and the Canal Zone. The group of donors was considered a representative sample of the permanent population. They had all been born on the Isthmus of Panama and had always lived there. They were persons not known to have experienced yellow fever. The donors are classified by age, sex and race in tables 1 and 2, and the results of the protection tests, classified by the ages of the donors, are given in table 5. Serums giving inconclusive results in the first test were retested once, and the second result was accepted if decisive. Without knowledge of the history of yellow fever in the Isthmus of Panama, a region from which the disease is now absent, this table might have been taken as evidence in favor of a maturation factor in yellow fever immunity, inasmuch as demonstrable immunity was found to be absent from the younger persons and present in many of the older ones. It happens, however, that the last known case of yellow fever on the Isthmus was in the year 1905, twenty-seven years ago, and all of the fourteen persons whose serums showed protective power were old enough to have been exposed prior to that date. None of the fifty-five serums from persons under 30 years of age gave protection.

THE SIGNIFICANCE OF INCONCLUSIVE RESULTS

In every large series of tests a certain minimum number of "inconclusive" results (those in which more than one and fewer than five mice out of six survive), arranged according to chance distribution, is to be expected and is of *no significance.* The *mortality* rate of mice in a series of our tests of known nonprotective serums was computed for us by Dr. H. Muench and found to be 0.879, or 87.9 per cent. With this mortality rate, the theoretical distribution of mouse survival ratios in 100 such tests would be as follows: 0/6 in 46 instances, 1/6 in 38 instances, 2/6 in 13 instances, 3/6 in 3 instances and 4/6, 5/6 or 6/6 in no instances. The number of serums giving "no pro-

tection" would be 84 per cent of the total, and those giving "inconclusive" results would be 16 per cent. None would give "protection."

CAUSES OF ERROR

If the strain of mice used in the protection test should be unsuitable because of low susceptibility to yellow fever virus, or if the virus in the suspension injected should be weak or insufficient in amount, there would be danger of getting false "protection," but ordinarily the controls would protect against these errors. If deaths should be occurring among the mice from other causes than yellow fever encephalitis, the tendency would be to get "no protection" with serums which are really protective. Unhealthy mice should not be used.

Properties of the serum may also be responsible for mistakes in concluding that the donor had previously been either nonexposed or infected. The serum may have deteriorated since the blood was drawn, or it may possess a degree of protective power not due to experience with the specific virus. Such protective power was not detected in our series of tests of known normal serums, except in one case in the Canadian series. In that case it was not high enough to give "protection" with regularity. Doubtless more "false positives" revealing this weak physiologic protective power of serum would be obtained if the test were made unduly sensitive by increasing the amount of serum used or by diminishing the amount of virus. Careful quantitative adjustments are necessary in every immunity test. The evidence here presented seems to show, however, that in the sensitive test under study the nonspecific physiologic protective power of serums from persons never infected with yellow fever virus is not strong enough to give false "protection," except in rare instances. The possibility of getting "no protection" exceptionally with the serum of persons who actually had yellow fever many years ago must also be taken into consideration.

Although mistakes due to the presence of physiologic protective substances, or to the loss of specific antibodies with the passage of time, probably do occur in rare individual instances and additional mistakes are made through errors of technic or the use of unsuitable animals, we are convinced that, when made with reasonable care, the test is remarkably specific and reliable, and that a positive test is strong evidence that the donor of the serum has previously been infected with yellow fever virus.

SUMMARY

The yellow fever protection test in mice, as an example of the immunity tests used in epidemiologic studies, was investigated for specificity and reliability. Serums of persons in Canada and China who could never have been exposed to yellow fever virus were tested for protective power against this virus. In only one instance was there any demonstrable nonspecific protective power and it was insufficient in amount to give protection with regularity. The test was found to be highly specific and useful as an indicator of past infection.

ABSTRACT OF DISCUSSION

DR. BOLIVAR J. LLOYD, Washington, D. C.: Epidemiologists will now be able to go into those places where yellow fever may have been present but unrecognized and be able to say definitely whether or not yellow fever has been present and just about how long. Conversely, they will be able to prevent false alarms. I should like to see Drs. Hughes and Sawyer go further with their experiments, as no doubt they will. I should like to know whether or not they can immunize on a large scale by giving their attenuated virus to human beings without the protection of immune serum.

DR. C. W. JUNGEBLUT, New York: The results of Drs. Hughes and Sawyer go far toward justifying the conclusion that endemic resistance to yellow fever, as determined by the neutralizing power of the serum, is essentially due to an acquired specific immunity. However, in my opinion it would be hazardous, on the basis of this one unusually illuminating example, to rely indiscriminately on serologic tests in epidemiologic studies. The normal human serum contains a large variety of substances capable of reacting with just as large a variety of antigens. Since Buchner's discovery of alexin, immunologists have tried in vain to explain the origin of these mysterious so-called normal antibodies and their relationship to typical immune bodies. This constitutes one of the most pressing problems in modern immunology. Certainly some of these antibody-like agencies, such as trypanocidal or anthracocidal substances, for instance, cannot possibly have been formed as the result of previous exposure to the specific antigen. In acute anterior poliomyelitis the question as to the nature and origin of the virucidal substances encountered in normal adult serums is unsettled. With such a limited incidence of the disease and such a restricted morbidity, knowledge of the actual dissemination of the infectious agent remains speculative. Utilization of the serologic test in an inverse manner as a means of judging previous contact with and by implication the immunizing effect of the virus is neither justified by clinical experience nor supported by experimental facts. Moreover, the statistical information yielded by such tests is not at all consistent. In my own work I have failed to recognize any convincing relation between density of population and absence or presence of the virucidal property. Through Dr. Sawyer's courtesy I have been able to examine some of the same Chinese serums just reported as lacking virucidal power against yellow fever virus, for their capacity to inactivate the virus of poliomyelitis. I have also had the opportunity of testing a small number of serums collected from isolated Eskimo tribes in Greenland. All of these serums have neutralized the poliomyelitis virus. Those who assert the specific nature of the immune bodies against poliomyelitis virus will find it difficult to reconcile these observations with the complete or practically complete absence of epidemic poliomyelitis in either China or Greenland.

DR. C. A. MOHR, Mobile, Ala.: I should like to ask the authors to state briefly under what conditions the blood of persons who are supposed to have had yellow fever can be used for experimental purposes. How it is transported?

DR. W. A. SAWYER, New York: Dr. Jungeblut has spoken of the danger of applying the results obtained in yellow fever immunity tests to other diseases and drawing the conclusion that in none of these other diseases, poliomyelitis in particular, does one get definite evidence of immunity, by accepted tests, in persons who have not previously been immunized by infection. His position is logically sound, but, unless populations can be found which can be shown to have been free from these other diseases since the birth of the present inhabitants, it will be unjustified to assume that the adults giving reactions indicating immunity have not been previously exposed to the corresponding specific infectious agent. Every immunity test used in epidemiologic studies should be quantitatively adjusted so that it does not give positive tests in persons who have not been exposed. If immunity tests are made unduly sensitive, the number of "false" positive and inconclusive results becomes considerable and difficult to interpret. We hope that Dr. Jungeblut will be able to find the explanation of some of the differences between unexposed individuals in the extent to which they possess the "normal antibodies" responsible for such reactions. As far as I am aware, it has not been clearly shown that complete or partial reactions of immunity in unexposed animals or persons have any demonstrable relation to susceptibility to the corresponding disease. In our experience with rhesus monkeys we find that the serums of certain normal animals give partial protection against yellow fever virus, but nevertheless on subsequent inoculation most of these monkeys are found to be definitely susceptible. In closing, I shall answer the question of

Dr. Mohr. Serum from a person who has recovered from yellow fever at any time in the past will usually have demonstrable protective power against yellow fever virus. If sterile, such serum will retain its antibodies at ordinary temperatures long enough to be sent by mail to our laboratory from anywhere in the United States. Any one wishing to cooperate in our investigation by sending serum should send enough for the tests —not less than 10 cc.

PRINCIPLES OF TREATMENT IN THE COMMON ARTERIAL DISEASES OF THE EXTREMITIES

W. J. MERLE SCOTT, M.D.
AND
JOHN J. MORTON, M.D.
ROCHESTER, N. Y.

Clinical interest in a given field is usually proportional to its therapeutic possibilities. Consequently, it is not surprising that until recently the common arterial diseases of the extremities have attracted comparatively little attention. Thus one of the leading systems of medicine, in its 600 page volume dealing with diseases of the heart, blood vessels and blood, devotes just four pages to chronic arterial diseases. And thrombo-angiitis obliterans is not even mentioned! With but few exceptions, internists and surgeons have neglected this problem of the common peripheral arterial diseases. Dr. Finney's comment at a surgical clinic that any one can amputate a leg, but that it takes a good physician to save one, has long been true. Yet in the past, investigations of peripheral arterial disease have been chiefly concerned with the end-stages. Attention has been focused on the extremity showing actual or threatened gangrene. Before this time arrives, a certain fatalism has characterized the attitude of the medical profession toward these conditions. It is true that since Buerger directed attention to presenile arterial thrombosis on an inflammatory basis as distinguished from senile or diabetic arteriosclerosis, this clinical differentiation has been made fairly successfully. It is also true that many different remedies have been proposed for the treatment of thrombo-angiitis obliterans. However, specific treatment of the peripheral arterial diseases based on an anatomicopathologic classification has been disappointing. There is no treatment for thrombo-angiitis obliterans as such. The outcome of the disease and the effect of the various forms of therapy depend on a physiologic function, namely, the state of the local circulation, and not on the anatomic condition of the main arteries. The predominant importance of function rather than structural change in the peripheral vascular diseases has received recognition in their study only in the last few years.

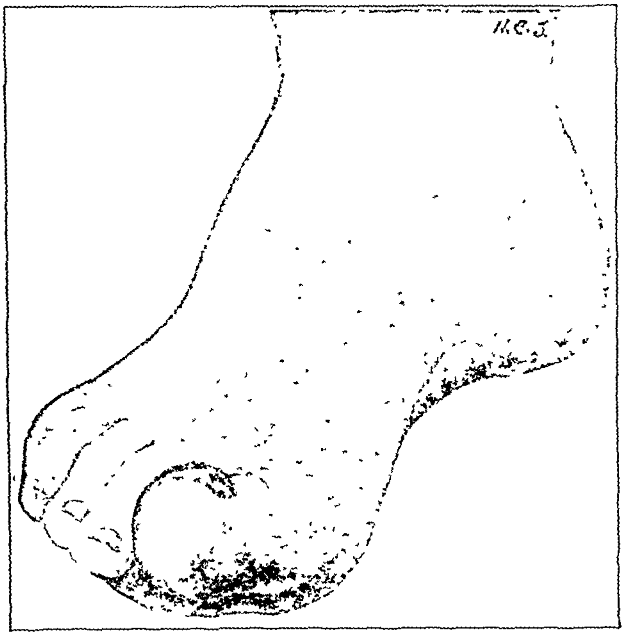

Fig. 1—Thrombo-angiitis obliterans. Physical signs present obvious evidence of circulatory impairment (ischemic areas with adjacent rubor). They do not demonstrate whether the deficient arterial supply is physiologically dependent on vasoconstrictor spasm or on mechanical occlusion.

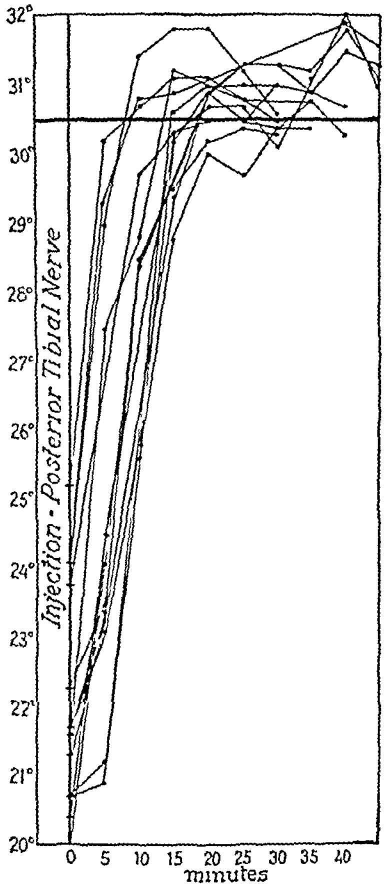

Fig 2—Response of the normal peripheral circulation to nerve block The temperatures in the distal, anesthetized part of the extremities come up to approximately the same level under standard conditions. (All measurements of surface temperature were made with the Tycos dermatherm.)

Brown-Séquard, and, soon thereafter, Raynaud, pointed out that persistent arterial spasm could result in serious circulatory impairment in the extremity, even leading to gangrene. The rôle of such vascular spasm in producing the ischemic paroxysms of Raynaud's disease is common knowledge. However, only in the last few years has it been shown that spasm is an important element in many instances of the common arterial diseases in the extremities. Since the recognition of this significant fact and the development of satisfactory methods for determining the vasoconstriction in the clinical syndromes, much progress has been made in treatment. The attitude of hopelessness in regard to peripheral arterial disorders should be abandoned. In place of the previous fatalism there are emerging certain definite principles of treatment in these conditions.

Whatever the type of the common arterial disease, when symptoms are produced they are dependent on an impairment in the local circulation. Such a circulatory deficiency is recognized by its symptoms and the signs elicited through ordinary methods of physical examination. The most important of such symptoms and signs are claudication, pain or other sensory

Read before the Section on Pharmacology and Therapeutics at the Eighty-Third Annual Meeting of the American Medical Association, New Orleans, May 13, 1932.

changes, dependent rubor, work and postural ischemia, the angle of circulatory efficiency, the absence of arterial pulsation, trophic changes, etc. Thus the clinical examination determines whether or not there is a local circulatory deficiency (fig. 1). When this deficiency is present it is dependent on one or both of two factors affecting the arteries, viz., first, mechanical obstruction, and second, vascular spasm. The differentiation of these two elements as the cause of the circulatory deficiency requires a special test.

TEST FOR SPASM AND OCCLUSION

The simplest and most direct method of determining whether vasoconstriction is present is by observing the effect of temporarily paralyzing the sympathetic vasomotor fibers. This is most conveniently performed by using local anesthesia to interrupt the vasoconstrictor pathway at some point between the central nervous system and the terminal vessels.[1] When this is done in the normal person, there is a marked increase in the local circulation as soon as the vasoconstrictor nerve fibers are paralyzed. It has been found that under standard conditions the circulation in the distal part of the extremity reaches approximately the same level in all normal persons (fig. 2). In occlusive arterial disease without spasm there is no increase in the deficient flow of blood under such conditions (fig. 3). But if vasoconstrictor spasm plays an important rôle in the production of the circulatory impairment, the blood flow is also improved in the anesthetic field. An important point under such circumstances is whether or not the local circulation rate reaches the normal level. If it does, the circulatory impairment is entirely dependent on spasm. If it does not, the amount by which it fails to reach the normal level, as measured by the surface temperature, represents the contribution of mechanical occlusion (fig. 4). This simple test determines whether vasoconstrictor spasm or mechanical occlusion is responsible for the circulatory deficiency in the extremity, or, if both are present, the relative significance of each. In every case of peripheral arterial disease, irrespective of the clinical diagnosis, it is essential to determine the relative proportions of these elements before a rational basis for treatment can be established. In different stages of the same disease, the proportions may change greatly. Thus it is our experience that most cases of thrombo-angiitis obliterans early in the disease usually show a considerable element of spasm, and that this is often the determining factor in the ischemia at this time. Later, however, the thrombotic process may become so extensive that we find an insignificant amount, or absence of spasm (fig. 5). Yet the diagnosis of the disease has not changed. All arterial disorders in the extremities require not only a diagnosis of the anatomic condition but also an evaluation of the physiologic state of the local circulation.

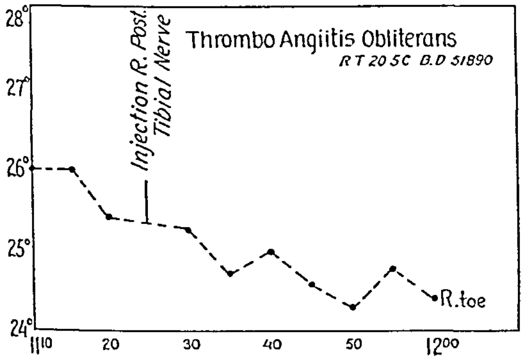

Fig. 3.—Thrombo-angiitis obliterans. The circulatory deficiency in this case is due solely to mechanical occlusion. There is no increase in the flow of blood after nerve block.

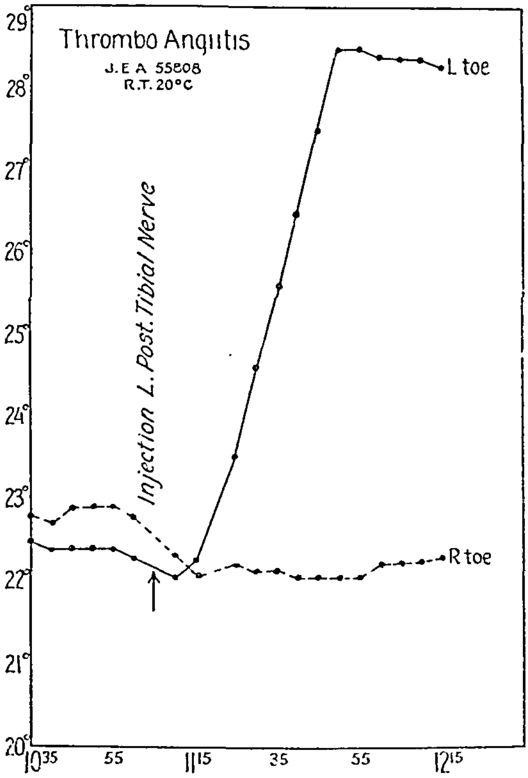

Fig. 4.—Thrombo-angiitis obliterans. Vasoconstriction is chiefly responsible in this case for impairment in the local blood supply. After anesthetizing the nerve the increased temperature of the surface demonstrates the improved local circulation.

TREATMENT

Treatment should always be directed first toward preventing the ischemia from doing more harm than necessary. This is a general principle and applies to all cases irrespective of their cause. Under this heading come such simple but important measures as rest, postural treatment and exercise, relief from pain and, particularly, scrupulous prophylaxis against infection.[2] The choice of other measures, however, depends on the presence or absence of spasm. When occlusion is shown by a functional test to be the causative factor, then at present there is no way to augment greatly the diminished flow of blood to the extremity. In such cases, the principle of treatment is to aid the more peripheral distribution of the small amount of arterial blood available. We have found venous ligation to be the most valuable procedure for this purpose.[3] This is no panacea in the treatment in this group of cases, but it appears to be of benefit in cases in which the circulation is not hopelessly inadequate. On the whole, however, the prognosis in this group is much poorer than when there is a large element of spasm.

---

[1] The basis for and the technic of this test have been recorded in our previous publications. Scott, W. J. Merle, and Morton, John J.: Sympathetic Activity in Certain Diseases, Especially Those of the Peripheral Circulation, Arch. Int. Med. **48**: 1065 (Dec.) 1931; The Differentiation of Peripheral Arterial Spasm and Occlusion in Ambulatory Patients, J. A. M. A. **97**: 1212 (Oct. 24) 1931.

[2] The importance of these general measures and their application is well outlined by Dr. A. W. Allen (Ann. Surg. **92**: 931 [Nov.] 1930).

[3] The results of this treatment as used in our clinic have recently been reported. Pearse, H. E.: The Use of Vein Ligation in the Treatment of Arteriosclerotic and Diabetic Gangrene, J. A. M. A. **98**: 866 (March 12) 1932.

In the latter group, the most important principle of any treatment adopted is to overcome, either temporarily or permanently, the arterial spasm. Various methods to accomplish this purpose have been used. Among them are, particularly, sympathetic denervation, either at the level of the chain or in the peripheral nerves, fever-producing injections, local or general hyperthermia and the use of vasodilating drugs. The more conservative measures, such as the use of drugs and of local heat, have proved unsatisfactory for effective control of arterial spasm. The immoderate use of tobacco has long been suspected clinically of being detrimental. Coller has recently shown that it causes definite vasoconstriction. Certainly tobacco should be denied these patients, at least in excess. This prohibition, even when carried out by the patient, is not sufficient to overcome the vasospasm already present.

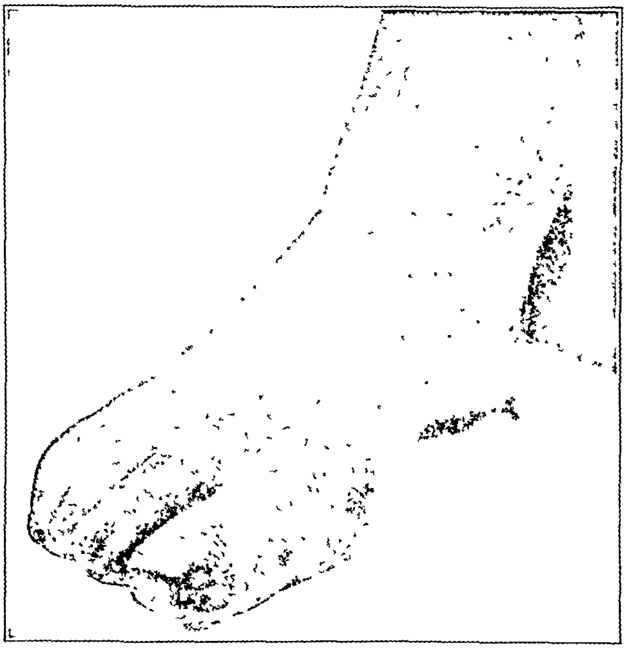

Fig. 5—Thrombo-angiitis obliterans The left leg was amputated eleven years previously There is marked dependent rubor in the right foot and a patch of dry gangrene on the great toe (Figure 3 shows the response of this patient to nerve block) This is the late stage of thrombo-angiitis obliterans, when the extension of the thrombotic process completely overcomes or obscures the spastic element.

Vasomotor denervation of the lower extremity by lumbar sympathetic ganglionectomy produces a continuous improvement in the local circulation to the same degree as was caused temporarily by the test with local anesthesia.[4] This operation is the procedure of choice in the young or middle-aged adult when the clinical evidence of a local circulatory deficiency and the functional importance of vasoconstrictor spasm are clearly established. The one important objection to this form of treatment is that it requires a major operation. The peripheral vasodilatation accompanying the systemic reaction to the injection of protein or inorganic chemicals has been advocated as a method of treatment in the milder cases in place of surgical intervention. The effect lasts from a few hours to several days. This method would be useful as a substitute for operation in the older group of patients concerning the condition of whose myocardium there may be some doubt. It is exactly in these patients, however, that the dangers of such reactions become greater. Consequently, it does not help in the more difficult decision as to the method of choice for overcoming spasm. For these patients, paravertebral injections of alcohol have been advocated. This procedure probably does not give permanent relief; it is usually followed by rather severe neuritic pains, and would make a later operation, if necessary, much more difficult. Periarterial sympathectomy does not have sufficient merit to warrant its use in such cases. Injection of alcohol into the peripheral nerves below the main muscular branches[5] not only relieves pain, but may result in improvement in the local circulation when the latter is impaired by vasoconstrictor spasm. The two objections to this method of accomplishing the latter purpose are: First, anesthesia in the peripheral area accompanies the vasomotor paralysis. Second, vasoconstrictor innervation to the vessels is reestablished in a few months. This method, however, is helpful in some difficult cases when operation and fever-producing injections are absolutely contraindicated by the patient's condition. The one procedure that permanently overcomes the detrimental effects of sympathetic vasoconstriction in arterial disease is sympathetic ganglionectomy. We hope some day to have a simpler method of removing as satisfactorily arterial spasm in the extremities.

ABSTRACT OF DISCUSSION

Dr. Rudolph Matas, New Orleans: The medical profession is indebted to Drs. Scott and Morton for their constant efforts to determine the rôle of vasomotor spasm as a cause of arterial obstruction and particularly for devising a simple and practical method of differentiating between spastic and arterial obstruction in the lower extremities. Their method determines not only the existence of spasm but also the extent or degree to which this contributes to the arterial obstructions. Until lately it has been necessary to depend on general or spinal anesthesia and the injection of typhoid vaccines and other fever producing substances to obtain the information that is now readily furnished by the simple posttibial block devised by Scott and Morton. From the therapeutic point of view, stress has been laid on sympathetic ganglionectomy, radicotomy and periarterial sympathectomy as the most certain and permanent means of obtaining vasomotor dilatation and in this way improving the capillary and arteriolar circulation in all cases in which spasm is a contributing factor in the ischemia. But it is not possible to disguise the fact that a lumbar ganglionectomy or radicotomy is a serious operation which is not applicable to all patients even when physiologically indicated. Neither is the repeated induction of fever with typhoid vaccines always a satisfactory mode of treatment. As long as these peripheral circulatory diseases cannot be dealt with etiologically, the only hope of relief and prolonging the life of the dependent parts lies in the control and arrest of the vascular spasm and in the stimulation of the collateral circulation. But before resorting to the traumatizing radicotomies and ganglionectomies, one should exhaust all the simple and safer methods of physical therapy (postural exercises, heat, contrast baths, vascular gymnastics, alcoholization of nerves, irradiations, the so-called synthetic fever). In line with these suggestions, I would direct attention to the irradiation of the lumbar region with x-rays as a vasodilator procedure. These irradiations, recently advocated by Langeron and Desplats, Morin, Brunet, Zimmerman and others in France, are directed to the suprarenals and probably act on the lumbar ganglions as well. The authors quoted report relief in intermittent claudication, Buerger's disease and threatened arteriosclerotic gangrene. Further trial of angiodilating drugs, such as acetylcholine and the muscle extracts introduced by J. S. Schwartzman of Odessa and M. S. Schwartzman of London (1931), is to be encouraged. Such vasodilating agents are helpful in relieving pain, retarding gangrene and, when this is established, permitting more conservative amputations. Little benefit is to be expected from the preventive ligation of the popliteal vein in chronic obstructive circulatory disorders of the legs. The effect of popliteal ligations are certainly too transitory in arteriosclerotic disease; and when the veins are obstructed, as in thrombo-angiitis, this procedure is positively harmful. The ligation of the satellite vein coincidentally with arterial ligations is subject to special and well defined indication and there is no justification for the present tendency to the indiscriminate ligation of the satellite vein as a routine procedure. There is much that I could say in regard to other questions brought up by the paper of Drs. Scott and Morton, but I have only time to congratulate the authors and their American co-workers on lifting this important division of surgery from an empirical to a highly scientific plane.

---

[4] Our results in substantiation of this point have been presented before the American Surgical Association (The Quantitative Determination of Vasoconstrictor Spasm as a Basis of Therapy in Peripheral Arterial Disease, Ann. Surg, 1932, to be published).

[5] This procedure has been presented in a useful, systematized form by Smithwick and White (Surg., Gynec. & Obst. **51**: 394 [Aug] 1930).

DR. EDGAR V. ALLEN, Rochester, Minn.: Massive gangrene of an extremity as a result of arterial disease is a stage which is comparable to the metastasis of cancer and represents a calamity which is largely avoidable. Not only is it essential that these diseases be studied extensively in medical centers but the average practicing physician must have the benefit of such studies. The feeling of hopelessness should be abandoned. The paper of Drs. Scott and Morton represents, therefore, a valuable contribution. I feel that great care should be taken regarding nomenclature. The authors speak of vasoconstriction and I should like to ask whether spasm is really present or is it rather absence of maximal vasodilatation. Nature is said to be provident, but her failure is evident in arterial diseases of an occlusive nature; tissue dies from an inadequate blood supply; often an increased blood supply is available but not utilized. Some investigators view the state of the arterioles in occlusive arterial disease not as hypertonic, that is, spastic, but rather as isotonic in the sense that the arterioles in the normal extremity are not spastic but exhibit a tone that is indicated as normal. If the condition is really one of spasm, the term is correct; if not, a word that indicates lack of maximal dilatation should be coined. Simpler methods for influencing the sympathetic nervous system are needed. There is great need for an effective agent which will influence the fibers of the sympathetic nervous system in the region where vasodilatation is needed. What is needed is a drug such as has been suggested by Brown, which will paralyze the peripheral sympathetic nervous system, either temporarily so that such a drug may be used in much the same manner as insulin in diabetes, or semipermanently; that is, through the production of a neuritis of the peripheral sympathetic nervous system. My experience with roentgen irradiation over the lumbar or cervical sympathetic trunks has not been satisfactory. I am now trying direct irradiation of the hands and feet. If vasodilatation can be produced by irradiation of the sympathetic nervous system, why should it be given at an area far removed from that in which the major trouble lies? This is a fruitful period in the treatment of vascular diseases; advances are not linked solely with the name of any man but with groups of physicians.

DR. A. W. ALLEN, Boston: The management of peripheral vascular disorders in general has been neglected in times past, but a few enthusiastic individuals have attempted to treat these diseases, advocating one form of therapy or another; particularly is that true with regard to thrombo-angiitis obliterans. All these individuals have had some success. The various methods have something in their favor, but the keynote of their success is due to the fact that these patients are treated along general lines of hygienic measures, proper position of the extremity, more or less at the level of the heart, where the interchange of blood is at its best. These efforts have been successful, owing to the painstaking care of the patient. Thrombo-angiitis obliterans has a tendency to be a self-limiting disease; in a certain number of cases it does not progress, apparently, beyond a certain point, or the development of adequate collateral circulation keep pace with the disease. In the cases that show a high vasomotor gradient, the operations on the sympathetic nervous system as advocated by Adson certainly constitute the best form of therapy. Unfortunately, in cases of thrombo-angiitis obliterans there is a large group of patients who have a low vasomotor index and in whom this operation is perhaps of some use but does not relieve the pain of ulcerated lesions. Then one must resort to other methods. I have not had much success with vein ligation. I have, however, saved a number of extremities by alcoholic injection of the peripheral sensory nerves, and in this group of cases, hopeless to begin with, there have been a number of patients rehabilitated. The point which Dr. Edgar V. Allen has made about further studies along this line is, of course, important. The etiologic agent in thrombo-angiitis obliterans is not yet known, and, until it is, perhaps rational therapy in that direction cannot be instituted. The general measures that are best adapted for the comfort of these patients have been reported and should be studied by any one interested. Whatever else is done, whatever specific therapy is used, unless these general measures are used in conjunction, they are apt to result in failure.

DR. A. W. ADSON, Rochester, Minn.: In carrying out sympathectomy in cases of thrombo-angiitis obliterans, I have observed that if the patient complains of a lesion in one extremity, manifested by an ulcer, interference with the circulation in the opposite extremity is likely to be found, even though ulcers are not present, and that in performing a bilateral lumbar ganglionectomy, one has done something to check the progress in the opposite extremity. Yesterday I had occasion to report 100 consecutive cases of thrombo-angiitis obliterans in which operations had been performed in the Mayo Clinic. As is well known, our studies are made both by the medical and by the surgical groups, and with the exception of one case there has not been an advance of the disease to the opposite nonulcerated extremity. Dr. Barker, from the department of vascular diseases of the clinic, reviewed 240 cases of thrombo-angiitis obliterans; he learned that the incidence of amputation in the poorly treated cases was 25 per cent and that it was reduced to 14 per cent following active medical management. Reviewing the cases in which operation had been performed by Dr. Craig, Dr. Learmonth and myself, he found that it had been reduced to 5 per cent, showing that removal of the sympathetic chain or, rather, destroying the vasomotor fibers did play a tremendous part in improving the circulation and in the conservation of the extremities. Radiotherapy to the ganglions and to the vessels in the digits has proved to be of no value in the treatment of our cases.

DR. W. J. MERLE SCOTT, Rochester, N. Y.: We have tried acetylcholine, both in normal individuals and in individuals with proved vasoconstrictor spasm. I was unable to find that we did anything to those individuals, either temporarily or permanently. That is, we would get a little temporary rise in temperature occasionally, but nothing like the effect that is obtained from actually paralyzing the vasomotor fibers. In regard to ligation of the vein, certainly its results in the occlusive group are not at all of the same order as those following sympathectomy in the spastic groups. Pearce, who has reported the cases from our clinic followed for over a year, concluded that in a certain significant proportion of them the clinical results were improved by venous ligation; but that is a difficult thing to be certain of. There is no doubt that there is a temporary increase in the peripheral skin circulation. Dr. Edgar V. Allen brings up an important question, that of nomenclature. I think that most of the notions now current must be revamped, and certainly textbook classifications of vascular diseases. After we recognized Buerger's disease we found that it didn't necessarily occur in the Jew. Then we found that it occurred in other regions of the body and other organs. Then it was found that there could be calcification of the vessels in it, and so on. Now today I must confess that in at least 50 per cent of the patients who come to me with common presenile or early senile vascular lesions I cannot state positively whether they have thrombo-angiitis obliterans or whether they have some other form of vascular disease. But I can tell whether or not physiologically spasm is playing an important rôle in creating the circulatory deficiency. Dr. A. W. Allen has brough up what to me is the crucial point in the therapy of thrombo-angiitis obliterans; namely, the development of collateral circulation. I feel that the evidence available from our studies and those from other clinics strongly suggests that the most effective way of increasing to the maximum the collateral circulation in the spastic group is by sympathetic ganglionectomy. Dr. Morton and I have tried to bring out in this paper certain principles of treatment, and I think that those principles really are now beginning to emerge as something to guide us rather than the feeling of hopelessness, of not knowing what to do in the face of these difficult problems.

THE TRANQUILIZING POTENCY OF MORPHINE, PANTOPON, CODEINE, PAPAVERINE AND NARCOTINE

RESULTS OF TESTS ON THE RAT

O. W. BARLOW, Ph.D.
CLEVELAND

Sahli,[1] following the introduction of omnopon, expressed the opinion that the combination of the alkaloids of opium produced a stronger and more rapid action than morphine. Winternitz [2] administered large dosages of the residual alkaloids to man, and although he was able to produce narcosis without undesirable side actions concluded that morphine was quite superior if analgesia was required. Macht and his associates,[3] after an extensive study of the responses of man to graded electrical stimuli before and after the administration of a series of the opium alkaloids, reported that the order of analgesic power was morphine > papaverine > codeine > narcotine > and thebaine. Codeine was reported as quite inferior to either morphine or papaverine. Narcotine alone produced an initial hypersensitiveness which was followed by a slight analgesia. Nevertheless, combinations of narcotine and morphine (narcophine) were said to produce a better analgesia than did the morphine contained in the combination. Möhrke, in 1921, likewise reported that narcotine potentiated the analgesic action of morphine. Such claims in relation to narcotine have been confirmed and contradicted both clinically and experimentally. Proof of the greater analgesic properties of such preparations as pantopon or narcophine as compared with morphine rests on a very insecure basis, and it is quite suggestive, as stated by Sollmann in 1926, that the clinical dosages of narcophine, pantopon and morphine are almost exactly equivalent as to their morphine content.

An opportunity of investigating this problem objectively and quantitatively is offered by the persistent restlessness of rats when tied back down to an animal board. After a period of from fifteen to twenty minutes they become partially reconciled or convinced of their inability to escape, but the discomfort, anxiety and natural restiveness are reflected by periodic muscular movements in complete absence of noise or other exciting causes. Records obtained over a period of from two to three hours at wide intervals are quite constant, and no evidence of the training effects of this procedure was obtained. This animal, because of the constancy of its reactions, should serve as an excellent test object for the study of sedatives.

The marked tranquilizing action of morphine, as illustrated in figure 1, on the muscular movements or activity of rats under these conditions was used as a basis for comparing the sedative effects of a series of narcotic alkaloids under standard conditions which were comparable in certain respects to clinical conditions in which morphine is indicated. The restlessness ensuing from the enduring discomfort of the position and restraint is closely analogous to a wide range of distressful conditions against which morphine is used therapeutically, including pain, apprehension, dyspnea and cough.

METHODS

Normal adult albino rats were used in all experiments. The animals were tied in a supine position to small padded boards having the general contour of the body and fitted with a head guard consisting of a short length of brass tubing attached to an adjustable base. This guard extended over the head and neck, to the sternum, and although free movement of the head was possible, the animals were unable to injure themselves in attempts to free their legs from the thongs.

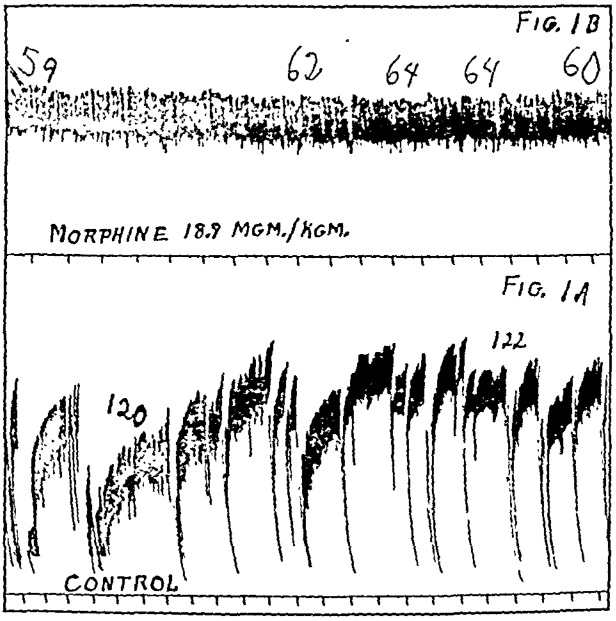

Fig. 1.—*A*, the respiratory (upstroke of lever indicates an inspiratory movement) and muscular movements of a normal rat when tied in a supine position. The time is in minutes. The respiratory rate per minute is indicated by the numerals above the tracing. *B*, the tranquilizing effect of morphine in a dosage of 18.9 mg. per kilogram (4.5 per cent of the minimum lethal dose) on the respiration and spontaneous movements of the same rat.

Graphic records of the respiratory and spontaneous muscular movements were obtained through the medium of a light lever connected with the skin just below the xiphoid process by means of a thread and a small bulldog clamp.

In a second series of experiments, the tranquilizing effectiveness of morphine and papaverine (as representative of the phenanthrene and isoquinoline groups of the opium derivatives) on the spontaneous movements was compared with that on the reinforced or painful reactions of the same animal when stimulated continuously by means of a subtetanic faradic current. Fine copper wire electrodes were wound around each hind foot and wet contacts maintained by covering the electrodes with cotton saturated with saline solution. Movements were recorded graphically from one (usually the left) of the hind feet by connecting the lever to one of the toes. Control records were obtained before and during stimulation. The stimuli were then discontinued

and the drug was administered. Sixty minutes later the procedures carried out during the control period were repeated.

The alkaloidal salts tested were dissolved in distilled water and the concentration adjusted so that the volume administered (subcutaneously) was relatively constant. The agents were compared as to equivalence with the morphine base over a range of dosages varying from 0.5 to 15 per cent of the minimum lethal dosage of morphine. Rest periods of from nine to twelve days intervened between successive experiments on individual animals to obviate the development of tolerance.

A series of from seven to fifteen rats were tested with each dosage of each of the alkaloids and pantopon. The average number of movements per minute over a period of from five to ten minutes were counted before, and again from sixty to eighty minutes after, medication. The median of the data for each series was obtained and the results were expressed in figures as percentages of the control activity.

RESULTS

Morphine.—The sedative effects of morphine were apparent with the minimal dosage tested (fig. 2 *A*). Movements were reduced 25 per cent with 2.1 mg. per kilogram of body weight. The degree of tranquilization increased with the dosage and was complete following the administration of from 19 to 21 mg. per kilogram. Such dosages are equivalent to from 4.5 to 5 per cent of the minimum lethal dosage (0.42 Gm. per kilogram) for the rat and in this respect correspond to a dosage of 15 mg., or one-fourth grain, for man.

Codeine.—The tranquilizing efficiency of codeine differs distinctly from that of morphine (fig. 2 *B*), although the form of the dosage curve is quite similar (in contrast to narcotine and papaverine, as illustrated in fig. 2 *C* and *D*). Twenty-one milligrams of codeine per kilogram of body weight reduced the spontaneous movements less than 10 per cent, while an equal quantity of morphine was completely sedative. The minimal tranquilizing dose of codeine (63 mg. per kilogram) was three times that of an equally effective dosage of morphine. However, 42 mg. of codeine per kilogram was 80 per cent sedative or, in other words, the near complete tranquilizing efficiency was only slightly less than one-half that of morphine. The potency relation therefore seems to vary somewhat with the degree of effect sought; i. e., codeine : morphine : : 1 : 2 or 3.

Narcotine.—Dosages of narcotine ranging from 4.2 to 126 mg. per kilogram were tested (fig. 2 *C*). No evidence of increased excitability was obtained over this range. The sedative effects noted were more variable and smaller in degree than with any of the other agents tested. The tranquilizing action was observed with the minimal dosage tested, but the rate of movement was reduced only approximately one third by the maximal dosage. The sedative efficiency of narcotine is probably less than one-fifteenth that of morphine. In dosages greater than the maximum indicated in the figure, an increased reflex excitability occurs so that the efficiency becomes even lower.

Papaverine.—The sedative effects of papaverine were apparent with all dosages tested. The efficiency increased but slightly with dosage and was incomplete even after medication with 126 mg. per kilogram of body weight (fig. 2 *D*). A numerical comparison of the tranquilizing effects of papaverine with those of morphine indicate that, on a weight basis, the one-half sedative efficiency of the former is approximately one-fifth, but for complete tranquilization the efficiency is considerably less than one-sixth that of morphine.

Pantopon.—The sedative effects of pantopon were compared with those of morphine on the basis of weight, therapeutic and actual morphine equivalence.

On the basis of weight, pantopon was one half as effective as morphine; i. e., a complete sedative action required 21 mg. of morphine or 42 mg. of pantopon per kilogram of body weight (fig. 3). On the basis of the advertised clinical or therapeutic equivalence, pantopon was less effective than morphine; i. e., the dosage of pantopon required for complete tranquilization was approximately 20 per cent greater than that usually accepted as being equally effective with morphine. This difference is exactly that which exists between the morphine content of a unit dosage of morphine and the corresponding therapeutic dosage of pantopon. No evidence was obtained that would indicate any significant activity on the part of the residual opium alkaloids contained in pantopon.

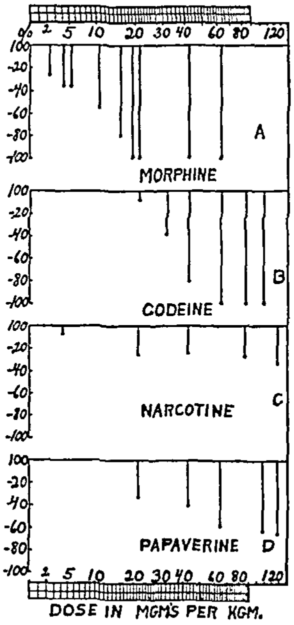

Figure 2

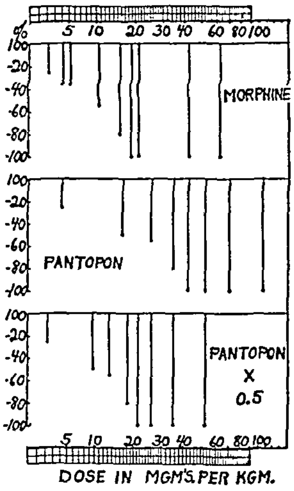

Figure 3

Figs. 2 and 3.—The data have been graphed on a semilogarithmic scale. The abscissas represent the dosages (subcutaneous) per kilogram of body weight. The ordinates represent the number of movements per minute in terms of percentage of the normal rate observed before medication.

COMPARISON OF THE TRANQUILIZING ACTIONS OF MORPHINE AND PAPAVERINE ON THE VOLUNTARY AND INVOLUNTARY MOVEMENTS OF THE RAT

Observations on the tranquilizing actions of morphine or papaverine on the "reinforced" or pain movements which occur during a constant stimulation of the legs of the rat by means of a subtetanic faradic current as well as on the spontaneous movements of the same animal in the absence of stimulation indicated no remarkable difference between the reactions to unit dosages of the two alkaloids under the two experimental conditions.

The reactions of the animals that were stimulated differed somewhat from those of the nonstimulated series, in that the continuous stimulation of the normal animal resulted in greater muscular activity (about five times normal) than occurred spontaneously in the absence of stimulation. Nevertheless, both the spontaneous and the "reinforced" movements disappeared after proper medication. Under such conditions, subnormal movements reappeared temporarily on beginning the stimulation but disappeared after from one to five minutes.

From the standpoint of simplicity as well as regularity of reactions on the part of the rats, the comparison of the spontaneous movements appear superior to that of the reinforced or pain reactions to electrical stimuli for studying the relative tranquilizing effectiveness of narcotics.

CONCLUSIONS

1. The depressant effects of pantopon and the several alkaloids on the spontaneous movements of the rat indicate that the sedative action of the series has the following order, from high to low: morphine > pantopon > codeine > papaverine > narcotine.

2. Morphine, pantopon and codeine in suitable dosages completely inhibited the spontaneous movements of the rat. Papaverine was only 50 per cent effective, while narcotine was practically ineffective. The dosage required for complete tranquilization as compared with morphine = 1; pantopon = 2, and codeine = 3. Papaverine or narcotine in dosages six times that of morphine (126 mg. per kilogram) produced only partial tranquilization; i. e., one half or less.

3. The sedative action of pantopon appears to be due solely to its morphine content.

CARBON TETRACHLORIDE POISONING

L. W. McGUIRE, M.D.
BOSTON

Carbon tetrachloride is used in industry as a solvent for gums, resins and fats; it is used as a dry cleanser and is a constituent of some of the rubber elements; it is used also to clean oil from machinery and, under the name of pyrene, as a fire extinguisher.[1] In medicine it is used as a vermifuge in the treatment of ankylostomiasis. Cases of poisoning have been reported from time to time. I have recently observed seven men who were affected by it, simultaneously, in a small plant where it was used as a solvent for cleaning.

Carbon tetrachloride (CCl_4) is a colorless, transparent liquid, like chloroform. It is insoluble in water and glycerin and is miscible with chloroform, alcohol and benzene. It is soluble in all fixed and volatile oils. It is volatile at ordinary temperatures but noninflammable.

Investigations as to the toxicity of carbon tetrachloride compared to chloroform have varied. Some investigators have reported it twice as toxic, and others about equally toxic.

It has been shown at the research laboratory of the bureau of mines[2] that, when carbon tetrachloride fire extinguishers are used in a closed room, subjected to high temperature such as would occur in a fire, deadly gases are formed. Phosgene gas, which is intensely poisonous, was formed in toxic quantities; chlorine in smaller amounts; hydrogen chloride also was formed, and there was considerable vapor of carbon tetrachloride. The experiments showed that it is extremely hazardous to employ carbon tetrachloride fire extinguishers on a hot fire in closely confined spaces.

Carbon tetrachloride, when used as a vermifuge, is not devoid of danger, especially in debilitated persons, persons addicted to alcohol, and those suffering from chronic cardiac, renal, hepatic and pulmonary diseases. Occasional poisonings have been reported, when used in therapeutic doses. Individual susceptibility plays a part.

Experimental work on dogs, by Minot and Cutler,[3] has shown that even in very large doses it did not produce an intoxication when the dogs were on a well balanced diet, that a comparatively small dose of the drug could produce fatal poisoning on a diet in which calcium was deficient, and also that cases of intoxication could usually be successfully treated by calcium therapy. They found that, on giving dogs from 3 to 4 cc. of carbon tetrachloride, per kilogram of body weight, made susceptible by a preliminary diet of lean meat without extra calcium, they usually had the following symptoms: In from fifteen to twenty hours there was slight malaise, some salivation and nausea, poor appetite, and diarrhea. After twenty hours the dogs became definitely ill and refused to move; there were some fibrillating tremors and visible twitchings of the paws and lips. Violent convulsions are sometimes seen; a foul, bloody diarrhea, with vomiting of changed or fresh blood, frequently occurs. They may go on to coma or profound weakness; death occurs in from forty-eight to sixty hours. The blood showed a hypoglycemia, with a retention of guanidine. The most obvious damage was in the liver. At autopsy, the liver appeared yellowish and was soft and friable. The gastro-intestinal tract usually contained old blood, with hemorrhagic areas in the pyloric end of the stomach and in the upper third of the small intestine. There is often some congestion noted in the kidneys. They also found that there was increased toxicity of carbon tetrachloride if alcohol was added to the diet.

They found that dogs poisoned by carbon tetrachloride could be successfully treated by intravenous injections of calcium chloride; that they would respond in from a few minutes to half an hour and become temporarily fairly normal, and that most cases could be permanently cured by a suitable course of calcium therapy. Calcium lactate could be given by mouth, if vomiting was not persistent. Ammonium chloride and hydrochloric acid were also effective, as well as parathyroid extract. The nervous symptoms were relieved and the blood sugar was restored to normal.

It was found that, by giving dogs a high calcium diet, with calcium lactate, for a period of from one to three weeks previous to administering the carbon tetrachloride, they were relatively immune to fatal poisoning.

In man, the most common symptoms reported in cases of poisoning, when administered as a vermifuge,[4] are nervous and gastro-intestinal irritability, as manifested by nausea, vomiting and diarrhea, accompanied by restlessness and periods of consciousness and unconsciousness, rise of temperature, and icterus due to its action on the liver and its appendages. This is due to fatty degeneration and necrosis of the liver cells, which is similar to that found in chloroform poisoning.

Keher and Onendal[5] reported five fatal cases due to its use as a vermifuge, in the Dutch East Indies. They found, pathologically, destruction of large segments of liver tissue, with pericentral necrosis. All the liver cells in the peripheral portions of the lobules were infiltrated with fat droplets or fat globules. There was an acute venous stasis of the entire portal system, which caused the vomiting of blood, and swelling in the gastric system, with petechia of the visceral serous membranes. There was congestion of the spleen, and degeneration of the renal tissue. Icterus developed in two of these cases. In one of the fatal cases, only 5 cc. was given. In the other four, a repeat dose had been administered. The authors note that users of alcohol were extremely sensitive to this drug.

Mauro[6] reports that the symptoms of poisoning are usually at first irritative phenomena of the eyes and of the throat; then cough, nausea, a sensation of burning in the epigastrium, vomiting, headache, cerebral excitation, and finally narcosis and coma. In cases that are not acute, these symptoms are not marked, and after a few days there may be gastrohepatic symptoms, with icterus.

The seven cases of carbon tetrachloride poisoning that I observed occurred among the employees of a felt manufacturing plant. The patients were all Italians and were wine drinkers. Carbon tetrachloride was used to remove spots from the felt. This method was changed, and instead of using it to remove the individual spot, a large amount, about a 33⅓ per cent mixture of carbon tetrachloride, was placed in the vats through which the felt was passed while the fluid was still warm. This resulted in the outbreak of poisoning, in a few days. The men all complained of nausea and vomiting, which lasted from one to three days. Three vomited small amounts of blood; six had diarrhea; none passed blood that they knew about; five complained of headache; four complained of burning or smarting about the eyes or mouth; two had definite liver enlargement with jaundice; four had evidences of kidney irritation, one of which was an acute nephritis. This man also had bronchopneumonia. All these men have recovered. One of the men with jaundice had an icteric index of 12, two months after the poisoning, the jaundice being entirely cleared. Two months later the icteric index was 4. Two months after exposure the icteric index in the others was normal.

The man with the bronchopneumonia and acute nephritis was critically ill. His symptoms from the onset were more severe. He started with nausea, vomiting and diarrhea. Fever soon developed. On the fourth day there was congestion of the bases. The pulse became elevated and weak; the blood pressure was 182 systolic and 102 diastolic; the white blood cell count was 27,000. The urine showed an acute nephritis and the lungs a widespread bronchopneumonia. He was transferred to a hospital, where his condition became desperate. His face was swollen and his tongue heavily furred; the breath had a urinous odor; he was very restless, continually crying out; his hands were cold and clammy; the pulse was very rapid, weak and irregular; the heart sounds were of poor quality; both bases were flat on percussion, with râles, squeaks and bubbles throughout both lungs. There was a diffuse, large, almost blotchy, macular rash over the greater part of his body; he was passing very little urine; death seemed certain. Under stimulation of epinephrine, caffeine sodiobenzoate and digitalis, with calcium lactate, he gradually began to improve and finally recovered. Four months after the exposure, he was up and about; his weight was normal, and he looked well. Physical examination at this time was negative. The liver was not enlarged. The icteric index was 5. He still complained of gastric distress and weakness.

CONCLUSIONS

1. Carbon tetrachloride may be, and often is, a serious poison.
2. The liver and the gastro-intestinal tract are the organs most commonly damaged.
3. Calcium deficiency and the use of alcohol render an individual much more susceptible.
4. Calcium therapy is particularly indicated in treatment.

SUBDURAL HEMATOMA IN INFANTILE SCURVY

REPORT OF CASE WITH REVIEW OF LITERATURE

B. BARRETT GILMAN, M.D.
AND
RADFORD C. TANZER, M.D.
ROCHESTER, N. Y.

The hemorrhagic diathesis of scurvy has been recognized since the time of Hippocrates. Hemorrhage occurs most commonly beneath the periosteum of the long bones and into joint spaces but frequently involves the skin, mucous membranes, orbits and serous cavities. Reports of hemorrhage associated with the meninges during the active scorbutic state are sufficiently rare to deserve note. The occurrence of subdural hemorrhage in a case of infantile scurvy, in which an operation was performed in this hospital, has led us to review the literature for similar cases.

Willis,[1] an English physician, in a treatise on scurvy published in 1668, mentioned the occurrence of intracranial hemorrhage in the course of this disease, an observation that was apparently based on pathologic examinations. Two hundred years later, in 1871, in a review of the pathologic anatomy of scurvy, Hayem[2] presented the first case of hemorrhagic pachymeningitis associated with scurvy.

To Sutherland,[3] however, must be attributed the first accurate clinical and pathologic report of this condition. In 1894 he described the case of a rachitic and scorbutic infant of 14 months who developed one month before death rigidity of the right arm, followed by an intermittent tonic spasm of the muscles of this arm and conjugate deviation of the eyes to the right. At autopsy there was found in the subdural space a dense, fibrinous mass, loosely adherent to the undersurface of the dura. Beneath this lay a layer of "soft, coagulated lymph," which was separated from the first tissue by a dense, white membrane. The spinal canal

likewise revealed a deposit of soft, reddened gelatinous material lying just beneath the dural covering. The same paper also includes the history of a 2 year old girl who, in addition to the usual picture of scurvy, presented on the second day of admission rigidity of the neck, dilated pupils, deviation of the head and eyes to the left and spasmodic contractions of the muscles of both arms. An autopsy the following day revealed a large blood clot over the superior surfaces of the brain bilaterally. This clot lay between dura and cortex (relation to arachnoid membrane not specified) and stained the surface of the cortex. The extravasation beneath the dura was evidently of some duration, as a considerable degree of organization was present. An additional finding of interest was the appearance of two subcortical hemorrhages, a condition not described elsewhere in the literature.

Several months later, Wallis Ord[4] reported before the London Pathological Society an autopsy record of a case of infantile scurvy, showing an extensive subdural hemorrhage occupying the whole cranial vault. Clinical signs of increased intracranial pressure had not been elicited.

In 1896, Meyer[5] described another true case of pachymeningitis hemorrhagica interna. The patient was an infant, aged 9 months, who presented clinical signs of both rickets and scurvy. No localizing neurologic signs were demonstrated, yet autopsy revealed on the under surface of the dura a fibrinous, hemorrhagic exudate containing localized accumulations of thin, watery fluid. The arachnoidal membrane was edematous, and both lateral ventricles showed slight enlargement.

A case of subdural hemorrhage in the spinal cord was reported by Feigenbaum[6] in 1917. The patient, a German soldier, aged 30, following a month's course of typical scurvy developed the signs of a transverse cord lesion of marked degree. Under adequate diet the external bleeding stopped, but neurologic signs showed no tendency to regress and the patient eventually died of sepsis. At autopsy a flat, partially organized subdural hemorrhage was discovered anterior to the cord, extending from the sixth to the tenth thoracic segment. There was also an extensive hematoma lying between the nerve roots in the subarachnoid space. Microscopic examination showed various stages of organization of a blood clot. The last two cases more nearly simulate the entity described by Virchow as pachymeningitis hemorrhagica interna than any of the other descriptions recorded here.

The last reported case of subdural hematoma was offered by Sammis[7] in 1919, occurring in a malnourished infant of 1 year, with unmistakable signs of rickets and scurvy. A general clonic convulsion was followed by death four hours later. Autopsy revealed a blood clot over the left postcentral gyrus, lying definitely between dura and arachnoid.

In addition to these seven recorded cases of subdural hemorrhage, we have found three reports of extradural bleeding in scurvy. Möller[8] in 1862 described a large extradural clot causing marked compression of the underlying cortex. The dura at this point was definitely thickened and displayed increased vascularity. Two similar cases were given by Sato and Nambu[9] in 1908 and by Glauber[10] in 1928.

Scherer[11] in 1913 reported thirteen autopsy records obtained within the course of a few months on young adults with scurvy, whose ages ranged from 20 to 25 years. Twenty-five per cent of the examinations revealed intracranial hemorrhage of one type or another. In none of the cases was there any evidence of trauma or of inflammatory change which might be considered of etiologic significance. The report did not include the relationship of the hemorrhages to the meninges but, judging from the description, they were probably extradural.

Several other contributions have been found presenting patients whose clinical picture suggested the presence of hemorrhage with pressure on the brain or cord. These cases lacked pathologic or operative confirmation. The American Pediatric Society's collective investigation of infantile scurvy in 1898[12] embodied a thorough study of 379 cases with 29 deaths. Cerebral hemorrhage was given as the cause of death, based on clinical evidence, in three cases. None of the six cases that went to autopsy showed any cerebral or spinal lesions. Hess and Fish[13] in 1914 mentioned a case under their care in which, during the course of the disease, twitchings of the muscles, convulsions and urinary bleeding developed. A lumbar puncture showed a blood-tinged spinal fluid, but no further evidence of the site of the blood clot or localized accumulation of fluid producing symptoms was to be had.

Von Noorden[14] in 1889 and Prakken[15] in 1925 each reported a case of scurvy characterized by the onset of neurologic signs of pressure on the spinal cord and disappearance under antiscorbutic treatment. Hemorrhage about the cord, though strongly suspected in both cases, was not definitely proved.

The cases herein reported indicate that cerebral complications in scurvy are unusual but by no means unknown. The 25 per cent incidence in Scherer's small group is surprising and not confirmed by other series. The most extensive collection of autopsies on scorbutic children which we have found is that of Sheldon,[16] numbering nineteen, in which no instance of intracranial bleeding was encountered.

Our case adds one more to the list of seven proved cases of subdural hemorrhage in scurvy, and it possesses the additional interest of being the first reported case in which the diagnosis has been confirmed by operation.

REPORT OF CASE

History.—E. M., an American boy, aged 16 months, was brought to the Strong Memorial Hospital, July 10, 1931, because of irritability and loss of appetite.

The patient was born spontaneously in the seventh month of pregnancy. The birth weight was 4½ pounds (2,041 Gm.). Breast milk was given for two months, followed by a sweetened formula of diluted pasteurized cow's milk for ten months. Whole milk was introduced during the four months prior to entry Cod liver oil had been given daily since early infancy Orange juice and tomato juice were given on an average of once a month because their more frequent use was associated with a recurring diarrhea Cereals and vegetables were not taken The general nutrition was considered consistently poor

At eleven months he had a bilateral, suppurative otitis media of one week's duration

The father and mother are living and well The Kahn reaction of the parents' blood is negative Two premature siblings are living and well One infant died thirty hours after birth

At 15 months of age, four weeks prior to entry, anorexia and general irritability became pronounced Tenderness of the lower extremities was noted at this time

Examination—The temperature was 37 6 C (99 7 F), the weight was 5 9 Kg (13 pounds) The child was poorly developed, dehydrated and slightly anemic The occiput was flattened and the fontanels were closed A slight bilateral internal strabismus was present The gums were congested A rather angular type of beading at the costochondral junctions was observed There was slight generalized enlargement of the lymph nodes The legs were tender and held in flexion and external rotation The right knee was swollen and painful on motion In other respects the general examination was not abnormal

The red blood cells numbered 4,400,000, hemoglobin was 55 per cent, the white blood cells numbered 12,600 The urine and Wassermann tests were negative Chemical examination of the blood revealed calcium, 10 6, phosphorus, 4 5, magnesium, 1 6 mg per hundred cubic centimeters A roentgen study of the long bones showed the characteristic picture of scurvy

Course—The child took daily from 30 to 90 cc of orange juice with potassium citrate and, for the anemia saccharated ferrous carbonate and copper sulphate During the next week the gums became normal, the extremities lost their tenderness, and roentgen evidence of calcium deposit in the long bones became manifest July 20, ten days after admission the temperature rose to 39 8 C (103 6 F), the white blood cell count was 20 600 and diarrhea occurred Nonprojectile vomiting was frequent during the next three days

July 25, the vomiting became projectile Twitching of the right side of the face and rolling of the eyes was observed, but further neurologic signs were not apparent until two days later, when internal strabismus increased and dilatation of the left pupil occurred Lumbar puncture revealed xanthochromic fluid under a pressure of 400 mm of water The diagnosis of left pachymeningitis hemorrhagica interna or of subarachnoid hemorrhage was made

July 28, a burr hole in the left parietal region was made under local anesthesia The dura appeared to be under moderately increased tension and congested When the dura was incised, about 60 cc of definitely xanthochromic fluid gushed forth The cortex was separated from the overlying dura by approximately one-half inch A drain was inserted to the subdural space and closure effected with silk

Postoperative laboratory studies showed a normal bleeding and clotting time A roentgenogram of the skull gave no evidence of subperiosteal hemorrhage

Following operation the strabismus decreased, the facial twitchings ceased and the patient became more alert The wound drained profusely until the removal of the drain, August 4 At this time the brain cortex was found to be almost flush with the dura Convalescence was delayed by several attacks of vomiting associated with loss of weight Lumbar punctures at intervals showed a gradual return of spinal fluid pressure to normal Following the removal of the drain the cranial wound was tapped daily Xanthochromic fluid was always obtained, at first under increased pressure, but gradually the normal dynamics returned

By the end of August the wound had healed the neurologic examination was normal the hemoglobin, aided by several transfusions had reached 75 per cent, and the patient was steadily gaining weight He was discharged, September 14

Except for a minor gastric disturbance shortly after discharge, the child has continued to improve No further neurologic changes have appeared Jan 6, 1932, when last seen, the internal strabismus was of the same degree as noted on the admission examination Mentally he was much brighter and more alert

SUMMARY

In a case of infantile scurvy, signs of intracranial bleeding developed during the period of hospitalization At operation a subdural sac of xanthochromic fluid was found and drained, with subsequent complete recovery

A review of the literature has revealed thirteen other proved cases of intracranial hemorrhage in scurvy, seven being subdural, three extradural and three unclassifiable Five of the seven cases of subdural bleeding were found in infants or young children

It is hoped that this emphasis will call attention to the possibility of intracranial complications in scurvy and to the advisability of early exploratory operation in cases presenting localizing signs of increased intracranial pressure

Clinical Notes, Suggestions and New Instruments

HEMOPHILIA PREVENTION AND TREATMENT OF BLEEDING WITH OVARIAN EXTRACT

H T Kimm, M D, and C M Van Allen, M D
Peiping, China

Following the announcement by Carroll L Birch[1] of the discovery that a hormonal disturbance exists in hemophilia which is temporarily relieved by parenteral administration of ovarian substances, the opportunity presented itself to us in a case of that disease to test the efficacy of ovarian extract for controlling dangerous spontaneous bleeding and to gather data of possible future assistance for safeguarding against persistently bleeding hemophiliac patients who need surgical operations The potential value to surgery of such clinical applications of Birch's discovery is obvious The data from this case are reported without waiting for more material since the disease is uncommon[2] and prompt standardization of the surgical methods will require that data from many sources be pooled in the literature

Birch gave daily injections of ovarian extract for eight months to one person with hemophilia and abolished the abnormal tendency to bleeding during that period and for two and one-half months afterward A second patient was treated by ovarian extract for one month and then received a graft of fresh human ovary into the anterior abdominal wall Examination of the blood gave normal results for five months Neither the dosage of the extract used nor the details of the effects on blood coagulation were published This investigator showed, furthermore that the urine of hemophilia patients differed from that of normal males by the absence in the former of appreciable amounts of female sex hormone

REPORT OF CASE

History—A Chinese boy, aged 10 years, had been admitted to the hospital twice previously in six years for uncontrolled bleeding from superficial abrasions The bleeding was stopped each time with great difficulty, chiefly by transfusions of whole blood but only after development of severe degrees of exsanguination The diagnosis of hemophilia was made from these symptoms and from the laboratory observations of marked delay in clotting time and clot retraction time, of normal bleeding time and of the normal number of platelets It was supported by the discovery that a younger brother had a similar history Other male members of the family could not be secured for examination A point of interest, which has

[2] Only two other cases have been seen in this clinic in ten years

been the subject of another report,[3] was that two years previously the patient received a blow on the flexor muscles of the right forearm and developed an intramuscular hemorrhage that led to a Volkmann's contracture. Three days prior to the present admission of the patient, he fell and scratched the lower lip, whereupon bleeding commenced and continued without interruption.

The boy was normally nourished and developed, but pale and weak. The lower lip was slightly swollen and presented a small slowly bleeding ulcer in the mucous membrane near the margin. The only other physical abnormalities were a faint systolic murmur over the heart and the Volkmann's contracture. The erythrocyte count was 2.7 millions, and the hemoglobin estimation (Sahli) 50 per cent. Since the diagnosis was already known and treatment was needed primarily, further blood tests were postponed.

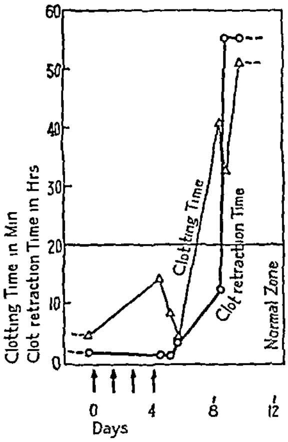

Chart 1.—Effects on blood coagulation of repeated intramuscular injections, once daily, of 4 grains (0.26 Gm.) of ovarian extract. Here, as in the other charts, arrows indicate the time of the injections.

Treatment.—An intramuscular injection of 4 grains (0.26 Gm.) of ovarian extract[4] was given at once. The bleeding became less rapid but failed to stop, and the injection was repeated at twelve hours. Bleeding ceased at fourteen hours but returned at twenty-four hours. A third injection at that time was followed in thirty minutes by permanent cessation of bleeding. One injection was then given every twenty-four hours for the next six days, and the ulcer healed rapidly. A dry dressing to protect the ulcer and routine nursing care constituted the only other forms of treatment. During the last four days of injections and the following six days, the blood was tested repeatedly for clotting time and clot retraction time.[5] The readings are given in chart 1. They were normal during the period of the injections and two days afterward. Four days after stopping the treatment the clotting time was prolonged to forty minutes, whereas the clot retraction time was still within the normal range. The day after that, both readings were abnormal, the clotting time being thirty-four minutes and the clot retraction time fifty-four hours. Six days after treatment was discontinued, both readings had assumed the high levels, i. e., fifty minutes for clotting time and fifty-four hours for clot retraction time, which proved to be natural to the patient. It was found from repeated tests during the fourteen days of rest that followed that the bleeding time[6] and platelet count[7] were normal, while the fragility of the platelets[8] was greatly decreased.

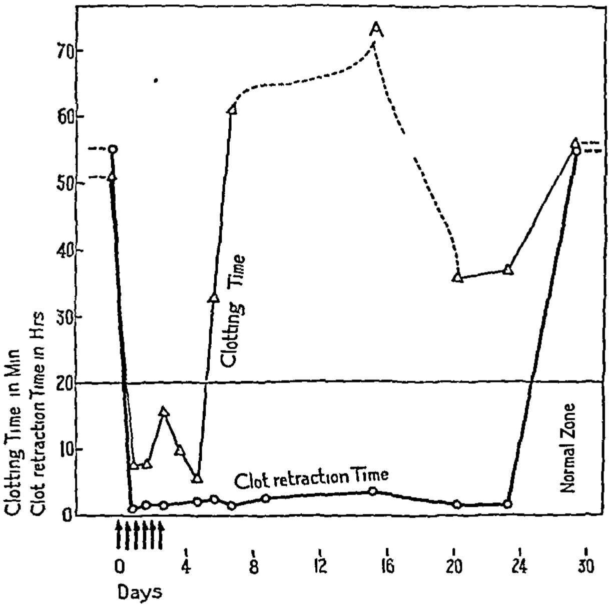

Chart 2.—Effects of repeated injections: twice daily, of 4 grains of ovarian extract. *A* represents 140 minutes.

Experiments in Prophylaxis.—After this the patient was without symptoms and largely recovered from anemia. He was induced to remain six weeks longer for the performance of three more tests as to the effects of intramuscular injections of ovarian extract. Other dosages than the dosage already given were used, and the experiments were separated by intervals sufficiently long to allow between the tests the blood to return to its natural state of coagulability, any probable accumulation of ovarian extract in the system to leave, and the punctured superficial veins to heal. The boy's veins were difficult of approach by needle at best, and phlebotomy was not justified, so the examinations had to be limited in frequency and confined to the more important considerations, namely, clotting time and clot retraction time. The results of the tests were as follows:

1. Six 4-grain doses were *given twice daily (chart 2)*. Before injection, the clotting time was fifty-one minutes and the clot retraction time was fifty-five hours. The next day, just before the third injection, both readings were well within the normal zone. The clotting time remained normal through the first five days, which was two days longer than the treatment lasted, then rose rapidly and reached approximately the initial level in two days. Readings were omitted after that until the fifteenth day, when the clotting time was more than twice as long as at first. This was followed by a swing back to points somewhat below the initial level and then by a swing up to the initial level. The clot retraction time remained normal throughout the period of treatment and for twenty days afterward. On the twenty-ninth day, it stood at the initial level.

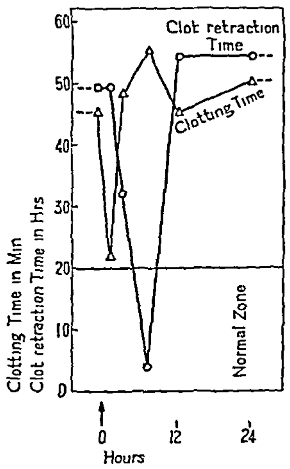

Chart 3.—Effects of one isolated injection of 4 grains of ovarian extract.

2. One isolated 4-grain dose was given (chart 3). Before injection, the clotting time was forty-five minutes and the clot retraction time, forty-nine hours. One hour after injection, the clotting time was twenty-two minutes, which was just above the normal zone, but the clot retraction time was unaltered. Then the value of the first function began to rise and that of the second to drop, until at seven hours they were fifty-five minutes and four hours, respectively, the first being distinctly above its initial level and the second being within the normal zone. At twelve and twenty-four hours, both values stood approximately at their initial levels.

3. One isolated 8-grain (0.5 Gm.) dose was given (chart 4). To begin with, the clotting time was sixty-five minutes, and the retraction time, thirty-six hours. One hour after injection the first value was slightly lower but still markedly abnormal, while the second was well within the normal zone. Practically the same values were found to exist for the next thirty-five hours. At sixty hours, the clotting was approximately at the

[8] Birch (footnote 1, first reference).

initial level, but the clot retraction time was still normal. At seventy-two hours, both readings had returned approximately to their initial levels.

CONCLUSIONS

Because venipuncture could not be done as often as required, the exact duration and extent of the effects of the injections on blood coagulability were not determined, but certain general influences were discerned:

1. Repeated intramuscular injections of ovarian extract influenced profoundly the coagulability of the blood of this hemophiliac patient; they stopped a hitherto uncontrolled and severe hemorrhage and they reduced the laboratory readings of blood coagulability to normal.

2. Isolated injections had definite but incomplete effects. At least two doses spaced from twelve to twenty-four hours apart were required to bring the laboratory readings to normal, and three doses in a period of twenty-four hours were necessary for permanent control of spontaneous bleeding. This suggested an accumulative action of the drug.

3. The effects of an isolated dose of 4 grains were practically the same in magnitude as those of one of 8 grains; the effects of a series of injections with 4 grains given once daily were the same in magnitude as those of a series with 4 grains twice daily. This was true of both clotting time and clot retraction time.

4. The effects of both isolated and repeated injections were maintained for some time after treatment was stopped, and they tended to be followed by a brief period with coagulation delayed longer than natural, before the coagulation returned to the natural state. The effects were maintained longer in respect to clot retraction time than to clotting time, after 8 grains than after 4 grains, and after twice daily than after once daily doses.

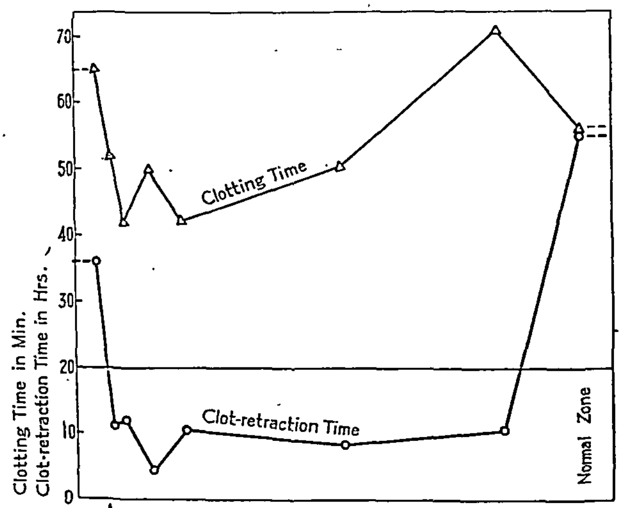

Chart 4.—Effects of one isolated injection of 8 grains of ovarian extract.

5. Experience with many more cases is required before the treatment and prophylaxis of bleeding in hemophilia can be standardized, but until this is at hand the following suggestions are made: Treatment may consist in intramuscular injections of 4 grains, begun immediately and continued at intervals of six hours until bleeding stops, and then at intervals of twenty-four hours until the wound is healed. The wound should receive the ordinary surgical care. Patients may be prepared for surgical operations by three injections, each of 4 grains of extract, the first being given twenty-four hours, the second twelve hours, and the third two hours before operation. If time permits, it might be better to give daily injections of 4 grains for two or three days before the operation, in addition to one injection two hours before operation.

SUMMARY

In a case of hemophilia, a prolonged period of spontaneous bleeding was terminated by intramuscular injections of ovarian extract and a series of experiments was performed to determine the effects of various doses of ovarian extract on the coagulability of the blood. The data obtained provided information of possible value in developing standard methods for prevention and treatment of persistent bleeding in this disease —bleeding that occurs from either accidental or surgical wounds.

OBSERVATIONS ON A PATIENT TO WHOM SPINAL ANESTHESIA WAS ADMINISTERED FIVE TIMES WITHIN THIRTY-EIGHT HOURS

William M. Sullivan, Jr., M.D., New York

The history reported here illustrates many interesting points in urinary physiology and suggests that spinal anesthesia, even though frequently repeated, is harmful only in proportion to the lack of skill of the anesthetist. The urologic history is long and has been greatly condensed.

R. M., a man born in 1891, a railroad employee, had hematuria and attacks of colic in the right loin for four years when, in 1922, the right kidney was removed. It was said to contain a large stone. The following year he had a urethral discharge, which continued until 1928. An abscess discharged through the perineum. In 1929 he was first seen by Dr. Keyes and operated on twice under spinal anesthesia (procaine hydrochloride) at a four weeks interval for urethral stricture and perineal abscess. Both lesions were relieved, though the perineum, after healing promptly and almost completely, still showed a pin hole fistula in the summer of 1930. Since that time many urethral instruments have been passed without encountering any obstruction and there has been no bladder retention of urine. The urethral and prostatic history has no bearing on the points under discussion.

In August, 1929, however, after brief pain in the left loin, he had anuria for twenty hours. The plain roentgenogram was negative, the pyelogram inconclusive as to the presence of stone and a normal kidney pelvis, but a number 6 ureteral catheter at 25 cm. up the left ureter passed a definite obstruction and drew 10 cc. of pus and urine.

An indwelling ureteral catheter was left for twenty-four hours. When this ceased to function the catheter was withdrawn and anuria recurred. Twelve hours later a vain attempt was made to reinsert the ureteral catheter into the kidney pelvis, and under spinal anesthesia (procaine hydrochloride) the left kidney pelvis was opened and a small urate stone milked upward from a point about 2 cm. down the ureter. There were many soft adhesions around the kidney at this time. The loin wound healed in twenty days.

In June, 1930, the renal symptoms recurred; and although a roentgenogram then was negative and the ureteral catheter drew clear urine which contained only scattered pus cells and detected no retention in the kidney pelvis, a month later phosphatic stones were visible to x-rays and by September had grown to fill the kidney pelvis.

With the growth of the stone the phenolsulphonphthalein output diminished from 25 per cent in thirty minutes after intravenous injection in June to 12 per cent in September. It has remained low since that time, varying from 8 per cent in September, 1931, to one count of 20 per cent in March of the same year. But during 1930, the nonprotein nitrogen of the blood remained approximately 40 Gm. per hundred cubic centimeters.

In view of the difficulty anticipated in reoperating on the left kidney and with the prospect of recurrence of renal stone, operation was deferred although the patient was becoming more and more incapacitated by irregular fever due to pyelonephritis and occasionally accentuated by left epididymitis and was bleeding from the kidney a good part of the time.

His chief complaint, however, was the great pain and frequency of urination. When this increased to every hour he was put in the hospital, in October, 1931, and bladder decompression was established. Within a week the bladder spasms were relieved but within a month they had recurred.

Nov. 12, 1931, therefore, he returned to the hospital worn out with pain, urinating three or four times an hour, usually with spasm, and passing urine which usually was bloody. Though his condition was considered desperate it is to be noted that from his normal weight of 170 pounds (77 Kg.) he had lost only 10 pounds (4.5 Kg.) and the nonprotein nitrogen, though it had been as high as 72 in September, was only 56 in October and 64 on entrance to the hospital.

For three days, bladder decompression was attempted in vain. Spasms in the bladder and hematuria were constant. In order to relieve the patient of his incessant pain, nephrotomy was done on the left kidney under nupercaine spinal anesthesia, December 15. The kidney was embedded in such extremely dense adhesions that the better part of an hour was spent in freeing its lower pole and opening into the lowest calix and removing a phosphatic stone from this. But the hilus had not been disclosed, nor the kidney pelvis, and the neck of the calix could not be found because of bleeding from the parenchyma. Therefore, no further attempt was made to extract the stone, and the operation was completed by suturing a small tube into the lower calix.

During the ensuing week the nonprotein nitrogen rose to 54, and the creatinine to 2.77, on the fifth day the patient was semicomatose but revived after an intravenous injection of dextrose. The urinary flow varied, sometimes chiefly from the loin, sometimes chiefly from the bladder. Hematuria was mild, the patient quite comfortable. The indwelling catheter was continued.

At 8 p. m., December 22, strangury returned and the bladder filled with clot. Nupercaine spinal anesthesia relieved the pain, and the clots were emptied out. This relief lasted but five hours, when the strangury recurred and a second spinal anesthesia again relieved this. A litholapaxy tube was introduced and no clots were obtained. This second spinal anesthesia gave relief for fourteen hours, at which time the pain again recurred and the third spinal anesthesia was given, which relieved him for eleven hours; then a fourth, which relieved him for six hours; then a fifth, at which time the bladder was opened suprapubically and a large quantity of blood clot emptied out of the bladder.

At this fifth spinal anesthesia within thirty-eight hours, the blood pressure before anesthesia at 11:20 a. m. was 122 systolic and 72 diastolic; after spinal anesthesia at 11:35 it was 120 systolic and 60 diastolic. It then rose at 11:40, as a result of the prespinal ephedrine, to 160/90 and the readings every ten minutes thereafter were 146/88, 152/82, 160/90 and 150/80 (at 12:20 p. m.). At 1 o'clock it was 140/70, at 1:30 it was 112/62 (pulse 120) and at 4:30 it was 108/40. The patient thereafter was entirely comfortable and suffered no inconvenience at any time from the spinal anesthesias. The spinal fluid cell count at the last anesthesia was 40, white and red cells mixed. The globulin showed a slight increase.

The patient made a rapid recovery; the loin wound healed. The suprapubic tube has remained in place and the urine has shown blood, but once the chemical examination of the blood has given normal results. December 29, Dr. Sheehan did a complete neurologic examination and was unable to find any reflex, sensory or other changes.

In March, 1932, the patient stated that he felt better than he had at any time in the last three years. He has not attempted to do any work.

COMMENT

1. Spinal anesthesia is used from time to time for the relief of acute ureteral or intestinal obstructions. The history given is contributed as evidence that it may be practicable to repeat the spinal anesthesia a number of times at short intervals without appreciable harm to the patient.

As stated at the beginning of this paper, the harm done by spinal anesthesia is probably proportionate to the lack of skill of the anesthetist.

2. The pathologic physiology of bladder and of renal retention and the relief of symptoms by splinting the bladder or by releasing insignificant obstructions is illustrated in many departments of urinary surgery. Thus, most treatments applied to the urethra or the ureter seem to owe their efficacy to mechanical rather than to chemical qualities. The striking and commonplace examples of this are the cutting of the urethral meatus to secure adequate drainage for the cure of chronic urethritis and the passage of the ureteral catheter to relieve infection of the kidney pelvis.

The case cited illustrates the adequacy of suprapubic drainage to relieve an intolerable situation. Repeated observations had shown that the bladder emptied itself always down to a few cubic centimeters. Under such circumstances and in the absence of bladder lesions, as certified by cystoscopy, there seemed every reason to believe that the repeated hemorrhages came from the kidney pelvis and that when the bladder splint (decompression), which had once subdued the symptoms for a short while, failed on a second trial the only hope of relief would be nephrostomy. Yet the event proved that, probably because the drainage by an indwelling ureteral catheter never quite kept pace with the hemorrhage, the suprapubic tube was required to abate the symptoms.

3. The patient is delighted, though not well. No great regret is felt that at the last operation on the kidney the stone was not all removed, for it surely would have recurred. From experience with similar cases in the experience of Dr. Keyes, it seems quite possible that the patient has a great expectation of life on condition that his physical exertions are somewhat restricted. The kidney is full of stone but its parenchyma is considerable in quantity and adequate in function. The stone has already set in such a way as to fill the pelvis and calices. It will be interesting to observe whether the little difference in facility of drainage through the suprapubic tube as compared to the urethra insures him for the future against the bleeding from which he has suffered so much in the past.

327 East Sixtieth Street.

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY OF THE AMERICAN MEDICAL ASSOCIATION HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS.
H. A. CARTER, Secretary.

CARRIER PORTABLE ROOM COOLER ACCEPTABLE

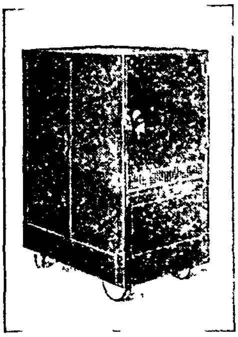
The Carrier Portable Room Cooler is manufactured by the Carrier-York Corporation, Philadelphia. Its purpose is to reduce the temperature of a hospital, a home or an office room to comfortable summer temperatures. It consists essentially of a cabinet resembling an ice chest and is equipped with two small motor driven air blowers designed to draw the room air by and in the presence of melting ice. No difficult installation is required; merely charge the cooler with ice, connect the cord to a source of current, and it is ready for use.

Externally, it looks like a piece of furniture and is usually finished in walnut grain or in ivory. The cabinet is 37⅝ inches long and 24⅝ inches wide. Its height is 52 inches and it weighs approximately 400 pounds without ice.

The cabinet is made out of steel, double thickness, and insulated. The insulation is pressed board type approximately one-half inch thick, the purpose of which is to prevent condensation or "sweating" on the outside of the cabinet.

The firm claims that 300 pounds of ice will operate the cooler at full capacity under hot weather conditions for about five hours. Regulation of the louvers on the air discharge will cause the ice to last longer but will cut down on the efficiency. The actual cooling is accomplished by two small blowers drawing the air from the room between the fins of a special metal grid on which the ice rests. The ice melts down between these fins in ridges and the air, coming in contact with the cold grid and the ice, is cooled. This cooled air is then distributed out into the room by means of the same blowers. The quicker the ice melts, the more the cooling. The rate at which the ice is melted determines the capacity of the unit. When the unit is not in operation, i. e., when the fan is not running, the ice in the cabinet melts, it is claimed, at the rate of from 4 to 6 pounds per hour. The manufacturer claims that at an average of 5 pounds per hour, only 50 pounds of ice would melt if the unit stood idle for ten hours.

The Carrier-York Corporation asserts that the cabinet has sufficient capacity to produce a comfortable summer condition in a room having 300 square feet of floor area with a 10 foot ceiling. Thus the room has a volume of 3,000 cubic feet. In larger rooms having unusually bad sun exposure, many electric lights or other equipment giving off heat, and a number of persons present, more than one unit may be required. Under no circumstances can a single unit be expected to cool satisfactorily a room of more than 4,000 cubic feet. Obviously, a ward in a hospital could not be cooled by one unit. Several units would be required.



Carrier Portable Room Cooler.

The cost of operation may be determined by applying to the local ice companies for the rates. Roughly, the rates vary from 20 to 40 cents per hundred pounds. At an average cost of, say, 30 cents per hundred pounds, one loading of 300 pounds would cost 90 cents, and if operated for the average period of, say, ten hours, the cost per hour would be 9 cents.

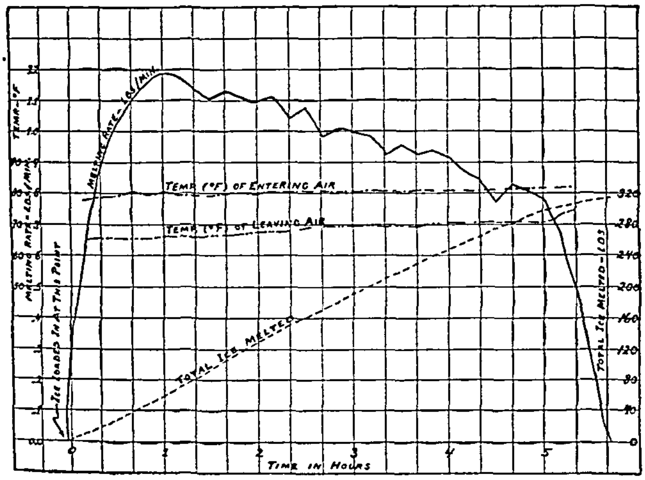
The motor is one-fiftieth horse power. It requires about the same amount of electrical energy to run as a 60 watt lamp. The approximate cost is 0.25 cent per hour.

The performance curve is shown in the accompanying chart. By a Council experiment, the curve was checked to within the limits of experimental error. The Council found that the temperature of the air passing through the unit was reduced from 9 to 12 degrees.

The same test shows that the blowers displaced about 500 cubic feet of air per minute.

A large compartment at the base of the unit affords storage space for the water formed by the melting ice, plus the moisture, which is taken out of the air. Hence the humidity in the room is reduced by the apparatus.

The manufacturer recommends three ways of emptying the water out of the base: First, wheel the cabinet to a floor drain and open the drain valve in the base of the cabinet. Second, use a simple water ejector which attaches to a water faucet and the water is sucked out of the cabinet. Third, use a portable self-contained pump and motor. The two latter accessories are extra and may be purchased from the firm. Usually the services of a janitor are required to empty the melted ice water and recharge the cooler with ice. By far the most convenient method is to allow the cooler to stand in a permanent place and have a regular floor drain installed.



Performance curve.

In a Council test carried out in a room of 2,200 cubic feet, the maximum outside temperature for that day being 90 F., it was found that the temperature in the room after the machine had been in operation for three hours was 77 F. The temperature in the adjoining room at the same time was 85 F. The relative humidity in the adjoining room was about 65 and in the room being cooled about 55. There was 30 square feet of window surface, south exposure. All the rooms surrounding it were not cooled. The occupant of the room stated that he was comfortable while the machine was in operation. There was a marked difference between the temperature in the adjoining room and in the experimental room.

The unit did not cool another room with about 3,344 cubic feet capacity and bad sun exposure, 60 square feet of window surface facing west and the room next to a flat tar paper roof. The company claims that two units would have been required for this room.

The manufacturer believes that the Carrier Portable Room Cooler will serve a therapeutic purpose in a "hospital operating room or dispensary" and that it will "provide comfort in a small individual patient's room either in a hospital or private home."

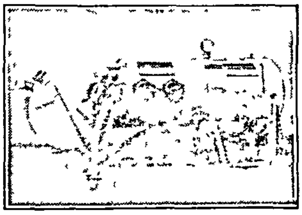
The Council declares the Carrier Portable Room Cooler eligible for inclusion in its list of accepted devices.

EMERSON DIAPHRAGM RESPIRATOR ACCEPTANCE

The Emerson respirator is an apparatus for producing prolonged artificial respiration and is manufactured by J. H. Emerson, 15 Brattle Street, Cambridge, Mass.

The machine is driven by an alternating or a direct current motor but may be operated by hand, if for any reason, such as failure of the current, this should be desired.

The body of the machine is a welded steel cylinder. Four windows made of cellulose acetate, "noninflammable" celluloid, are placed at advantageous points for observing the patient. Five portholes are located below the level of the windows for convenient care of the patient. These are provided with sponge rubber diaphragms, permitting the attendant's arms to be inserted into the respirator without interrupting its action.



Emerson respirator.

Sponge rubber collars supplied with the respirator are thick and flexible, and, according to the manufacturer, are comfortable for the patient. The respirator bed may be raised or lowered to center the patient's neck in the rubber collar. The bed, equipped with a sponge rubber mattress, is flat at all times.

A simple adjustment makes it possible to use either positive and negative pressure or negative pressure alone. The respirator is provided with a low pressure dial gage especially developed for this purpose.

Printed instructions for use and care of the machine are permanently placed in plain view on the side of each respirator.

Variations in pressure within the cylinder are produced by a double, heavy leather diaphragm. This diaphragm may be easily replaced if necessary. The mechanism activating the diaphragm is a standard worm reduction unit operated by a one-fourth horsepower electric motor. An adjustment is provided to vary the respiration rate anywhere between 15 and 35 respirations per minute.

Variation in speed is obtained by moving the motor nearer or farther away from a variable speed pulley; as the motor is drawn away from the pulley, the rubber V belt is pulled down closer to the center of the driven pulley, making it go faster. This variable speed pulley is attached to the shaft of a worm reduction unit (50 to 1), equipped with tapered roller bearings on both shafts. The worm reduction unit in turn drives a walking beam, which pushes the leather diaphragm in and out to create the variations of pressure inside the tank.

Moving parts are in plain view and accessible for care and oiling, and it is claimed that the operation is so simple that any hospital electrician or engineer should be able to understand and care for it.

Furthermore, the firm manufactures an infant model. The infant model is similar in operation to the adult respirator, including the hand operation feature and a small size dial pressure gage.

Additional attachments by the manufacturer have been developed for the adult respirator. An attachment can be supplied to raise the foot end of the respirator a maximum of 30 inches off the floor, giving a substantial tilt to the machine.

Another attachment can be fitted on the head end of the machine for continuing artificial respiration when the main body is opened. This attachment is operated by the respirator motor and therefore the respiration rate of the attachment synchronizes with that of the respirator.

The Council on Physical Therapy declares the Emerson Diaphragm Respirator acceptable for inclusion in the Council's list of acceptable devices.

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

The following additional articles have been accepted as conforming to the rules of the Council on Pharmacy and Chemistry of the American Medical Association for admission to New and Nonofficial Remedies. A copy of the rules on which the Council bases its action will be sent on application.

W. A. Puckner, Secretary.

HALIVER OIL WITH VIOSTEROL 250 D-ABBOTT.—Halibut Liver Oil with Viosterol 250 D-Abbott.—Halibut liver oil, adjusted by addition of maize oil to have a vitamin A potency of not less than 30,000 pharmacopeial units (U. S. P. X) per gram, and by addition of a sufficient amount of viosterol in oil 250 D to assure a vitamin D potency of not less than 250 D [250 times that of the standard cod liver oil defined by the Wisconsin Alumni Research Foundation (or 3,333 units [Steenbock] per gram)].

Actions and Uses.—The same as those of cod liver oil (See general article, Cod Liver Oil and Cod Liver Oil Preparations, New and Nonofficial Remedies, 1932, p. 271).

Dosage.—For infants, 8 to 10 drops (3 to 3.5 minims) daily; for premature and rapidly growing infants, 15 drops (5.25 minims) daily; for older children, 15 to 20 drops (5.25 to 7 minims) daily; for adults, especially nursing and expectant mothers, 20 drops (7 minims) or more daily. The marketed preparation is accompanied by a special dropper designed to deliver approximately 3 drops to the minim.

Manufactured by the Abbott Laboratories, North Chicago, Ill. U. S. patent and trademark applied for. The viosterol in oil 250 D used is manufactured under U. S. patent 1,680,818 (Aug. 14, 1928; expires 1945) by license of the Wisconsin Alumni Research Foundation.

Soluble Gelatin Capsules Haliver Oil with Viosterol 250 D-Abbott, 3 minims: Each capsule contains 3 minims of haliver oil with viosterol 250 D diluted with 3 minims of vegetable oil.

Haliver oil with viosterol 250 D-Abbott is prepared by combining halibut liver oil, maize oil and viosterol in oil 250 D in such proportions that the finished product will have a vitamin A potency of not less than 30,000 pharmacopeial units (U. S. P. X.) per gram, and a vitamin D potency of not less than 3,333 units (Steenbock) per gram. The halibut liver oil is assayed for vitamin A by the method described in the *Journal of the American Pharmaceutical Association* **19**: 616, 1930, and for vitamin D by the method of the Wisconsin Alumni Research Foundation (see under Viosterol, N. N. R., 1932, p. 424). The potency of the finished product is arrived at by a calculated dilution of the previously assayed oil, though some batches are biologically assayed.

PARKE-DAVIS HALIVER OIL WITH VIOSTEROL-250 D.—Halibut Liver Oil with Viosterol 250 D.—Halibut liver oil, adjusted by addition of maize oil to have a vitamin A potency of not less than 30,000 pharmacopeial units (U. S. P. X) per gram and by addition of a sufficient amount of viosterol in oil 250 D to assure a vitamin D potency of not less than 250 D [250 times that of the standard cod liver oil defined by the Wisconsin Alumni Research Foundation (or 3,333 units [Steenbock] per gram)].

Actions and Uses.—The same as those of cod liver oil (See general article, Cod Liver Oil and Cod Liver Oil Preparations, New and Nonofficial Remedies, 1932, p. 271).

Dosage.—For infants, 8 to 10 drops (3 to 3.5 minims) daily; for premature and rapidly growing infants, 15 drops (5.25 minims) daily; for older children, 15 to 20 drops (5.25 to 7 minims) daily; for adults, especially nursing and expectant mothers, 20 drops (7 minims) or more daily. The marketed preparation is accompanied by a special dropper designed to deliver approximately 3 drops to the minim.

Manufactured by Parke, Davis & Company, Detroit. U. S. patent and trademark applied for. The viosterol in oil 250 D used is manufactured under U. S. patent 1,680,818 (Aug. 14, 1928; expires 1945) by license of the Wisconsin Alumni Research Foundation.

Soluble Gelatin Capsules Parke-Davis Haliver Oil with Viosterol-250 D 3 minims: Each capsule contains 3 minims of haliver oil with viosterol-250 D, diluted with 3 minims of vegetable oil.

Parke-Davis haliver oil with viosterol 250 D is prepared by combining halibut liver oil, maize oil and viosterol in oil 250 D in such proportions that the finished product will have a vitamin A potency of not less than 30,000 pharmacopeial units (U. S. P. X.) per gram, and a vitamin D potency of not less than 3,333 units (Steenbock) per gram. The halibut liver oil is assayed for vitamin A by the method described in the *Journal of the American Pharmaceutical Association* **19**: 616, 1930, and for vitamin D by the method of the Wisconsin Alumni Research Foundation (see under Viosterol, N. N. R., 1932, p. 424). The potency of the finished product is arrived at by a calculated dilution of the previously assayed oil. Stability tests thus far reported indicate that the product will retain its potency when not exposed to extremes of light or of temperature.

NORMAL HORSE SERUM (See New and Nonofficial Remedies, 1932, p. 357).

The Cutter Laboratory, Berkeley, Calif.

Normal Serum (From the Horse). (See New and Nonofficial Remedies, 1932, p. 358).—Also marketed in bottles containing 100 cc.

Lederle Laboratories, Inc., Pearl River, New York.

Normal Horse Serum. (See New and Nonofficial Remedies, 1932, p. 358).—Also marketed in 30 cc. vial packages.

Committee on Foods

The following products have been accepted by the Committee on Foods of the American Medical Association following any necessary corrections of the labels and advertising to conform to the Rules and Regulations. These products are approved for advertising in the publications of the American Medical Association, and for general promulgation to the public. They will be included in the Book of Accepted Foods to be published by the American Medical Association.

Raymond Hertwig, Secretary.

HEINZ TOMATO JUICE

(Seasoned with Salt)

Manufacturer.—H. J. Heinz Company, Pittsburgh.

Description.—Pasteurized tomato juice with added salt; retains in high degree the vitamin content of the raw juice; packed in tins and bottles.

Manufacture.—Only the highest quality, carefully selected, vine ripened tomatoes are used; overripe or decayed fruit is rejected. The tomatoes are usually received at the factory within a few hours from the time of removal from the vine; they are thoroughly washed, selected, scalded with steam, trimmed of cores, underripe spots or other unsuitable material, and while still hot are passed to special pressure extractors in which the juice and more tender pulp are pressed out without the incorporation of air. This operation and all subsequent handling of the juice is carried out with as little exposure to air as possible. The juice is heated to 87 C.; a small amount of salt is added; it is filled into tins or bottles, which are sealed and processed at 87 C. for twenty minutes.

Analysis (submitted by manufacturer).—

	per cent
Moisture	93.3
Total solids	6.7
Ash	0.9
Salt (NaCl)	0.5
Fat (ether extract)	0.1
Protein (N × 6.25)	1.0
Crude fiber	0.3
Carbohydrates other than crude fiber (by difference)	4.4

Calories.—0.2 per gram; 6 per ounce.

Vitamins.—Biologic assay proves the product to retain in high degree the vitamin content of the raw tomato juice. The vitamin A content is more than 10 per cent of that of butter. Ten grams per day provides adequate vitamin B for normal growth of rats; 3 cc. of juice affords protection against scurvy in guinea-pigs, which is only slightly more than the quantity of orange juice required. Vitamin G is present in small amount.

Claims of Manufacturer.—This tomato juice is a good source of vitamins A and B and an excellent source of vitamin C. Especially prepared for table use and as a vitamin C supplementary food for infant feeding.

PURITY MILK BREAD

Manufacturer.—Purity Baking Company, Decatur, Ill.

Description.—A white milk bread made by the sponge dough method (method described in THE JOURNAL, March 5, 1932, p. 817); prepared from patent flour, water, powdered skim milk, sugar, butter (sweet unsalted), salt, yeast, malt syrup and a yeast food containing calcium sulphate, ammonium chloride, potassium bromate and sodium chloride.

Analysis (submitted by manufacturer).—

	per cent
Moisture (entire loaf)	37.6
Ash	1.9
Fat	2.7
Protein (N × 6.25)	9.9
Crude fiber	0.3
Carbohydrates other than crude fiber (by difference)	47.6

Calories.—2.5 per gram; 71 per ounce.

Claims of Manufacturer.—A milk bread of good quality.

DICKINSON'S LITTLE BUSTER HULLESS POP CORN

Manufacturer.—The Albert Dickinson Company, Chicago and Minneapolis.

Description.—Canned popcorn kernels with a proper moisture content for popping.

Manufacture.—Dwarf hullless variety of popcorn is raised under much the same conditions as is ordinary corn. The corn cobs with the husk partially removed are stored in outdoor specially constructed cribs for drying or "curing." The moisture content of the popcorn as it comes from the fields ranges from 16 to 21 per cent. The corn is air-dried until it assumes an average content of 12 per cent moisture. This natural curing requires from six to eight months, depending on the original moisture content and the weather conditions. The popping condition of the corn is determined by popping tests in which the increase in volume is carefully measured. The properly cured popcorn is shelled from the cob, cleaned by screening and winnowing to remove broken and imperfect grains and chaff, and automatically packed in hermetically sealed tins to preserve the popping quality.

Analysis (submitted by manufacturer).—

	per cent
Moisture	11.6
Ash	1.3
Fat (ether extraction method)	4.9
Protein (N × 6.25)	12.3
Crude fiber	3.0
Carbohydrates other than crude fiber (by difference)	66.9

Calories.—3.6 per gram; 102 per ounce.

Claims of Manufacturer.—Canned dwarf variety popcorn, guaranteed to pop.

GORMAN'S WHEAT BREAD

(66⅔ Whole Wheat Flour, 33⅓ White Flour)

Manufacturer.—Gorman's Bakery, Incorporated, Central Falls, R. I.

Description.—A whole wheat and white flour bread made by the straight dough method (method described in THE JOURNAL, March 12, 1932, p. 889); prepared from whole wheat flour, patent flour, water, sweetened condensed skim milk, sucrose, lard, yeast and salt.

Analysis (submitted by manufacturer).—

	per cent
Moisture (entire loaf)	36.7
Ash	2.1
Fat	3.7
Protein (N × 6.25)	11.1
Crude fiber	1.4
Carbohydrates other than crude fiber (by difference)	45.0

Calories.—2.6 per gram; 74 per ounce.

Claims of Manufacturer.—This bread supplies cellulose bulk to the diet as an aid to dietary laxation or regulation.

FISHER'S BLEND BRAND FLOUR (BLEACHED)

Manufacturer.—Fisher Flouring Mills Company, Seattle.

Description.—An "all purpose" short patent flour prepared from red and white wheats; bleached.

Manufacture.—Selected red and white wheats are cleaned, scoured, tempered and milled by essentially the same procedure as described in THE JOURNAL, June 18, 1932, page 2210. Chosen flour streams are blended, bleached with nitrogen peroxide and a mixture of benzoyl peroxide and calcium phosphate (1 pound to thirty-five barrels) and automatically packed in cotton sacks.

Analysis (submitted by manufacturer).—

	per cent
Moisture	13.2
Ash	0.39
Fat	1.0
Protein (N × 5.7)	11.4
Crude fiber	0.2
Carbohydrates other than crude fiber (by difference)	73.8

Calories.—3.5 per gram; 99 per ounce.

Claims of Manufacturer.—An "all purpose" short patent flour for general baking uses.

STORCK'S BREAD

Manufacturer.—Storck Baking Company, Parkersburg, W. Va.

Description.—A white bread made by the sponge dough method (as described in THE JOURNAL, March 5, 1932, p. 817); prepared from patent flour, water, dry skim milk, sucrose, salt, yeast, lard, malt syrup, and yeast foods containing calcium sulphate, ammonium chloride, sodium chloride and potassium bromate, and a mixture of calcium acid phosphate and calcium peroxide.

Analysis (submitted by manufacturer).—

	per cent
Moisture (entire loaf)	34.0
Ash	1.5
Fat	1.4
Protein (N × 6.25)	10.2
Crude fiber	0.2
Carbohydrates other than crude fiber (by difference)	52.7

Calories.—2.6 per gram; 74 per ounce.

Claims of Manufacturer.—A bread of good quality.

PURE CALIFORNIA EHMANN OLIVE OIL
PURE EHMANN OLIVE OIL

Manufacturer.—Ehmann Olive Company, Oroville, Calif.

Description.—Cold-pressed, unblended, olive oil.

Manufacture.—Mature California olives are harvested and delivered direct to the mill. Care is taken to prevent heating or molding through improper stacking of boxes of olives. The fruit is ground and pressed in hydraulic presses, which are adjusted so that the pit is not crushed. The expressed liquid is allowed to stand in settling tanks to permit separation of the oil, which is skimmed off, stored in tanks for several weeks and double filtered by gravity (a force filter or filter press is not used). The filtered oil is aged for at least six months and packed in bottles and tins. The oil is guaranteed not to contain in excess of 0.2 per cent free fatty acid as oleic acid.

Analysis (submitted by manufacturer).—

	per cent
Moisture	0.0
Fat (ether extract)	100.0
Free fatty acids (as oleic acid)	0.2
Specific gravity (15.6 C./15.6 C.)	0.915
Refractive index at 15.5 C.	1.4712
Iodine number (Hanus)	85.
Saponification number	190.
Unsaponifiable matter	1.4

Calories.—9.0 per gram; 255 per ounce.

Claims of Manufacturer.—A pure cold-pressed virgin olive oil for table and medicinal use.

WEIDEMAN BOY BRAND TOMATO JUICE

Manufacturer.—The Loudon Packing Company, Terre Haute, Ind.

Description.—This product is the same as Loudon Brand Tomato Juice (THE JOURNAL, June 25, 1932, p. 2289).

THE NATURE OF PROTEIN SOLUTIONS

The question of the nature of protein solutions has disturbed workers in the field for many years. On the one hand are the views advocated by such colloid chemists as Wolfgang Ostwald that the proteins are to be considered primarily as colloids and as such are incapable of forming true chemical combinations with other substances. Opposed to this view are the conceptions of such biologic chemists as Sørensen, Michaelis and Pauli, who consider the proteins primarily as amphoteric electrolytes, which, however, are unique in that they also exhibit certain colloidal properties because of their enormous molecular size. Recent investigations of these substances, carried out largely under the direction of Prof. S. P. L. Sørensen in the Carlsberg Laboratories, in Copenhagen, have led to conceptions of the nature of protein solutions which are bound to find important application in our ideas concerning the behavior and the function of the proteins in protoplasm. These investigations have been ably discussed and summarized in a recent publication by Sørensen.[1]

Studies of the behavior of the serum globulins led Sørensen, some years ago, to conclude that euglobulin and pseudoglobulin were reversibly combined in a loose chemical combination, E_pP_q, in which E and P represent euglobulin and pseudoglobulin complexes, respectively, combined in the relative proportions of p and q. Subjecting serum to such procedures as dialysis, or addition of ammonium sulphate, results in a shifting of the proportions of E and P with the resultant formation of less soluble and more soluble complexes of the two proteins. Sørensen failed to prepare, even after repeated fractionations, samples of either euglobulin or pseudoglobulin that were completely free from the other protein. These results with the globulins led to a series of investigations of other proteins with the result that apparently pure preparations of serum albumin, casein and gliadin were each found to consist of mixtures of an unknown number of proteins of similar character combined in a reversible manner. Such proteins, according to Sørensen, represent "reversibly dissociable component systems" and may be represented by the formula $A_XB_YC_Z$ . . ., in which A, B, C and so on represent components of a definite character and composition (e. g., polypeptides) and x, y, z and so on indicate the number of such components in the complex system. In each component, atoms or groups of atoms, such as amino-acids, are linked together by means of strong chemical bonds, whereas the complexes are formed by the union of many components through weak, residual valences. Chemical or physical agents that act on the chemical bonds produce irreversible changes in the protein molecule, whereas the residual valences readily respond to changes in salt concentration, p_H or temperature, in a reversible manner. Although the fractions obtained by the various fractionation methods employed possess the essential properties of the initial material, they exhibit variations in physical properties and chemical composition that are best considered as being due to the varying amounts of the individual components in each fraction. In no case thus far studied has Sørensen succeeded in isolating a component capable of resisting further fractionation by appropriate methods.

In biologic fluids, these simple protein complexes combine, by means of their residual valences, not only with complexes of the same kind but also with other complexes present in the system. In serum, for example, are probably found not only those systems, such as albumins and globulins, which may be isolated by suitable precipitation methods, but also mixed systems containing both of these substances combined in varying proportions not only with each other but with other serum constituents, such as the lipids.

These conceptions of Sørensen account for the extraordinary difficulties encountered in the isolation of reproducible protein systems from such complex biologic fluids as serum or egg white. They also serve to explain results obtained by Svedberg[2] and his collaborators, using entirely different experimental methods. Svedberg finds, for example, that there is no substance in fresh egg white with a molecular weight which corresponds to that of crystallized ovalbumin, but that this substance appears only after the egg white is treated with ammonium sulphate, as in the crystallization process. Similarly, a protein with the molecular weight of lactalbumin appears in milk only after treatment with ammonium sulphate. In the case of serum, Svedberg finds that half saturation with ammonium sulphate precipitates globulin having a definite molecular weight and that the euglobulin and pseudoglobulin appear when this substance is subjected to further fractionation processes. These results of Svedberg, when interpreted in accordance with the conceptions of Sørensen, indicate that the simple proteins with which we are familiar exist in nature only as part of more complex systems. The difficulties of the protein chemist are increased enormously for, in addition to extracting from complex biologic mixtures, by standardized methods, component systems that are reproducible, it now becomes essential to develop methods for the separation of these systems into their individual components. The determination of the nature of these comparatively simple components must await further progress in this important field.

[2] Svedberg, T.: Molecular Weights of the Proteins in Their Native State, Nature **128**: 999 (Dec. 12) 1931.

There still remains to be pointed out some of the effects which these new conceptions of the nature of protein solutions must have on the interpretation of laboratory work involving the proteins and, more generally, on one's picture of the part these substances play in protoplasm. Such determinations as albumin-globulin ratios, for example, are probably dependent largely on the nature of the complexes present in the serum and must be considered from this point of view. In protoplasm, instead of relatively inert, independent, colloidal particles, there are probably complex systems in equilibrium with one another and constantly shifting in response to changes in environment. The multiplicity and flexibility of these systems are probably of profound importance in determining the adaptability of the organism to its environment.

CORRELATION OF BLOOD DYSCRASIAS ON HYPOTHESIS OF BONE MARROW DEFICIENCY

New data concerning the blood and blood forming organs has given renewed impetus to progress in hematology. As a result of the development of much material, classification of separate syndromes is being attempted on the basis of causative factors and pathogenesis. Unfortunately, the etiology of most blood dyscrasias is not definitely known. The recent tendency of those interested in clinical hematology is to focus attention on the pathology of the blood forming organs. This fundamental approach yields valuable information. Moreover, in recent discussions on hematology there has been a tendency to substitute rigid systems of classification for rational descriptive analyses of each dysfunction.

Lescher and Hubble[1] have attempted to correlate disorders of the bone marrow with a group of conditions in which the blood elements are deficient. These include agranulocytic angina, idiopathic purpura hemorrhagica, pure red cell anemia and idiopathic aplastic anemia. They propose a nomenclature to emphasize the common pathogenesis of aplasia or hypoplasia of bone marrow deficiences. Aplastic anemia, in which all three elements are deficiently produced, should be known as myelophthisis; agranulocytic angina, in which there is defective formation of granulocytes, as granulophthisis; the rare cases of pure red cell anemia, as erythrophthisis; and one group of purpura hemorrhagica as thrombophthisis. It is their opinion that this nomenclature emphasizes the connection between these disorders and indicates their origin as bone marrow deficiencies. As the authors point out, these diseases are of fundamental importance because they compel consideration of the bone marrow function and the factors that normally stimulate and inhibit the production of blood elements. Such a conception also has virtue in emphasizing a difference in prognosis when the clinical picture may be indistinguishable.

Although Lescher and Hubble present an excellent critical review of various theories of the pathogenesis of these disorders, it is questionable whether enough that is definite has been developed to justify the use of the proposed nomenclature. Conclusive evidence is not presented that the changes in the bone marrow are as clear cut as they indicate. In the cases of agranulocytosis that Schultz first reported, involvement was not noted in the erythropoietic or megakaryocytic elements. Subsequent case reports by other observers, however, indicated that the pathologic changes in the bone marrow were not so sharply defined in all cases and that anemia and hemorrhage may sometimes be present. Variation in the clinical picture and response to therapy have also been noted. Neither is it established that any group of idiopathic purpura hemorrhagica can be attributed solely to deficient production of platelets by the bone marrow. In some cases megakaryocytes are reported as actually increased in the bone marrow; in others they are morphologically and functionally changed and in another group they are reduced. It has not been possible to separate these cases on the basis of clinical and pathologic observations. The authors suggest that thrombopenic purpura may eventually be divided into two or more groups in which there is (1) a deficient production of megakaryocytes or (2) a defective separation of the platelets from the megakaryocyte. If platelet production alone is involved in the pathogenesis of idiopathic purpura hemorrhagica, it is difficult to understand why patients who undergo splenectomy eventually have a low platelet count but are free from purpura. An improved functional capacity of platelets after splenectomy, which might be used as an explanation, has never been adequately demonstrated except by inference. The authors review the various objections to attributing hemorrhage solely to platelet reduction and consider the part which pathologic changes of the capillaries may play in the production of symptoms. They apparently feel, nevertheless, that there is one group of idiopathic purpura hemorrhagica which may develop solely on the basis of deficient platelet production.

The disorders enumerated are striking examples of the impossibility of defining clearly any disorder of which the etiology is unknown. Indeed, it is difficult to arrange isolated observations regarding the disease in any orderly sequence without the proper conception of cause and effect. While it is of value to examine data critically from time to time as the authors have done, it is apparent that the time is not yet ripe for a correlation of a group of disorders of the blood and blood forming organs whose pathogenesis is still in doubt. Such premature correlation minimizes the divergent features which demand study and may serve to inhibit or to give a wrong trend to rational therapy.

"VIRULENCE CYCLE" IN EPIDEMICS

Ancient clinicians used to feel that the demon responsible for a specific epidemic hibernated in the underworld. Then, emaciated and ravenous, it fought its way past the holy ramparts into the city, where it fed first on defenseless infants, later on the stronger adults. Finally, satiated, it lost its lust for human flesh and retired for another hibernation. Modern clinicians consider this merely a fantastic explanation of the observed course of epidemics. However, L. T. Webster [1] asserts that many of our current epidemiologic theories are nothing more than thinly disguised paraphrases of this ancient demonic metaphor.

Bacteriologists of the Pasteur-Koch era intuitively translated many ancient traditions into the newly developed language. They assumed, for example, and apparently without realizing the necessity of experimental proof, that specific infectious agents are always introduced into a community in an attenuated form and are subsequently increased in virulence or infectivity by successive human passage. After the "peak" of the resulting epidemic, the virulence was assumed to lessen, presumably as a result of microbic conflict with the resistant population. With a final almost total loss of virulence, the epidemic ceased.

This virulence cycle found some support in the increased infectivity of old test-tube cultures on successive animal passage, and in the usual initial low virulence of certain natural viruses when transferred to another animal species. Recognizing the inadequacy of such evidence, however, Webster and his colleagues made careful comparisons of the virulence of the specific causative agents in the various stages of their experimentally produced epidemics, all tests being made in the same animal species. To their surprise they found that in their carefully quarantined mouse and rabbit populations the virulence of the specific causative agents remained practically unchanged throughout all epidemics. "In no instance were significant differences in the virulence of preepidemic, epidemic and postepidemic strains detected. . . . Strains from fatal cases proved to be of the same virulence as similar strains from healthy carriers." Bacterial dissociation and bacteriophage phenomena, although abundantly present, seemed to play no part in altering virulence, or in otherwise limiting the spread of infections. The Rockefeller Institute workers, of course, did not generalize from these observations that virulence changes may not play a part under other experimental conditions. Their results, however, have definitely shifted the burden of proof to clinicians who champion the conception of "virulence cycles" in epidemics.

Webster and his co-workers emphasize the importance of the initial dose of specific infectious agents in relation to the general resistance of a population. The reduction of general resistance, for example, by the introduction of low resistant immigrants was sufficient to cause a latent epidemic manifest only by subclinical cases or carrier states to flare up into a devastating pestilence. Depression of general herd resistance by climatic conditions or by dietary deficiencies caused similar explosive outbreaks. Optimal diets or dietary reinforcements with butter fat or cod liver oil tended to prevent or at least lessen herd mortality.

It was an essential part of the Rockefeller Institute technic to produce herd epidemics through natural portals of infection. Their results, therefore, seem to represent complete immunologic pictures including the combined results of portal defenses and internal protective factors.

Current Comment

THE CONTENT OF CHOLESTEROL IN THE BLOOD

A fundamental feature in the application of various chemical "constants" of the fluids of the body to the needs of clinical diagnosis lies in the dependability of the data that are employed. Departure from the "normal" figures can then be utilized for conjectures as to the existence of abnormal conditions. Thus, it is essential to know definitely about the variability in the content of the blood sugar during health and under customary changes in routine and regimen, before a proper interpretation can be given to analytic results that deviate from "average" records. There are diurnal variations in body temperature that must not be mistaken for indications of ill health. For many body "constants" the permitted range of variation that is physiologic has been well established. Much remains to be accurately ascertained. During recent years attention has been focused by many clinicians on the cholesterol content of the blood. There have been numerous reports of deviations from the normal with attempts to associate them with special types of disease. One may almost say that a cholesterol cult has arisen even before the physiologic rôle of this unique lipid has been established. How much remains to be done before any well established norms are available has been indicated by recent studies of Bruger and Somach[1] at the New York Post-Graduate Medical School. They show that the cholesterol content of the blood examined under strictly comparable laboratory conditions—an important detail—is by no means constant from hour to hour, even in the fasting state. In fact, healthy persons may show practically the same degree of variation as is found in the blood in pathologic states. Contrary to what many have been led to expect, the ingestion of food is reported to have no appreciable effect, either immediate or late, on the cholesterol content of the blood. In general the figures are lower in the morning; hence it is suggested that cholesterol studies be carried out then. For the present one is forced to concede that normal persons may undergo variations in the content of blood cholesterol which are of the same magnitude as those found in pathologic states. According to Bruger and Somach, this statement must be modified only for those clinical conditions which accompany severe cachexia or apply to patients at the point of death.

Association News

MEDICAL BROADCAST FOR THE WEEK

American Medical Association Health Talks

The American Medical Association broadcasts on Monday and Wednesday from 10:45 to 10:50 a. m. over Station WBBM (770 kilocycles, or 389.4 meters). The Columbia chain program has been discontinued for the present.

The subjects for the week are as follows:

September 19. And Then the Schoolboy.
September 21. The Father of Surgery.

There is also a fifteen minute talk sponsored by the Association on Saturday morning from 10:45 to 11 over Station WBBM.

The subject for the week is as follows:

September 24. Obesity.

This schedule is based on Chicago daylight saving time, one hour faster than central standard time.

QUARTERLY CUMULATIVE INDEX MEDICUS

Volume 11, 1932, of the *Quarterly Cumulative Index Medicus* has just appeared. It represents the first issue since this publication was taken over completely by the American Medical Association. The book is published at considerable loss and represents a contribution by the American Medical Association to the advancement of medical science. In a desire to make the publication satisfactory to its principal users, a letter was sent early in July to all libraries subscribing to the *Index*, asking the opinion of librarians as to the desirability of publishing a special edition of the *Index* on 100 per cent rag paper so as to give it permanence. Three hundred and eighty-four letters were sent to domestic, foreign and Canadian librarians, and approximately 50 per cent of the librarians addressed have replied up to this time. Approximately 6 per cent of the librarians indicate a desire for a special edition and a willingness to pay for such a special edition at an advanced rate.

With the issuing of the present volume, arrangements have been made to improve the binding greatly without, however, increasing the cost of the *Index*. The binding now used has greater strength and durability than the one formerly used.

Because of the relatively small number of librarians indicating willingness to subscribe to the rag paper edition, it has been decided not to issue the *Index* in this form.

The majority of letters received from librarians contain high praise for the *Index* as produced and commendation for the Association in publication of this work. One librarian writes, "Just as the sterilizer is the center of the hospital so is the *Quarterly Cumulative Index Medicus* the center around which the medical library revolves."

The letters from the librarians also indicate that most medical libraries are at this time undergoing great financial strain and relatively little expansion.

Medical News

(Physicians will confer a favor by sending for this department items of news of more or less general interest: such as relate to society activities, new hospitals, education, public health, etc.)

CALIFORNIA

University News.—The Rockefeller Foundation recently made available to Stanford University a gift of $200,000 to promote research in the social sciences. This research has been supported for a number of years by the Laura Spelman Rockefeller Memorial Fund. Seventy-five thousand dollars of the total, which is to be distributed over a five year period, is unconditional. The remainder will be granted on the condition that the university provide an equal amount from other sources.

Campaign to Enforce Egg Standardization.—The August 27 issue of the bulletin of the state department of health notes that city and county health officers of California are assisting in a campaign to enforce the law pertaining to the standardization of eggs. One hundred thousand copies of an explanatory digest of the law have been distributed. The law is designed to establish standards by which the consumer can purchase eggs and be certain of their quality and size. The educational campaign was begun by the food and drug enforcement division of the state health department.

Change in Military Instructors.—As a result of the economy bill passed by the last congress, Col. William A. Powell, professor of medicomilitary science and tactics, University of California Medical School, has been relieved of his duties after eight years' service. Col. Cosam J. Bartlett, U. S. Army Medical Corps, stationed at the Presidio, has been placed in charge of medicomilitary science and tactics at the medical school to see that those students already started in the curriculum are allowed to complete it. As soon as the present medical students are graduated, the subject will be discontinued, unless national finances improve in the meantime.

GEORGIA

Society News.—Dr. Charles Usher, Savannah, among others, addressed the First District Medical Society, August 3, on "Massive Collapse of the Lung," and Dr. John William Shearouse, Savannah, "Transurethral Prostatectomy."——Dr. Benjamin H. Minchew, Waycross, addressed the Ware County Medical Society, August 5, on "Physiology of Squint."——The Twelfth District Medical Society, at its meeting in Vidalia, July 7, was addressed, among others, by Dr. Cleveland Thompson, Millen, on "Practical Treatment of the Common Neuroses."——At a meeting of the Randolph County Medical Society in Cuthbert, August 3, N. Meredith DeJarnette, Atlanta, spoke on "Arsphenamine Poisoning."——Speakers before the Muscogee County Medical Society, August 11, were Drs. Otis D. Gilliam and James H. McDuffie, Jr., both of Columbus, on ruptured appendix and amenorrhea, respectively.——Dr. Allen R. Rozar, Macon, discussed "Fractures in and Around the Elbow" before the Macon County Medical Society, August 2.

ILLINOIS

Society News.—The Massac County Medical Association was host to the fifth quarterly meeting of the Southwestern Kentucky Medical Society in Metropolis, August 23. Speakers were Drs. Charles E. Gilliland and Paul B. Nussbaum, St. Louis, on newer aspects of pancreatic diseases and cancer, respectively.——The St. Clair County Medical Society was addressed, September 7, by Dr. Joseph P. Costello, St. Louis, on "Common Disorders of Childhood." Dr. Daniel L. Sexton,

---

[1] Bruger, M., and Somach, I.: The Diurnal Variations of the Cholesterol Content of the Blood, J. Biol. Chem. 97:23 (July) 1932.

Dr. Robert [illegible] Library

St. Louis, addressed the society, September 1, on "Practical Value of Present-Day Endocrine Therapy."——Dr. Philip H. Kreuscher, Chicago, addressed the Fulton County Medical Society, August 24, on "Fractures of the Elbow and Hip."——Dr. William H. Olmsted, St. Louis, addressed the Madison County Medical Society, September 2, on "Arteriosclerosis of the Lower Extremities with Particular Reference to the Treatment of Diabetic Gangrene."——Dr. Henry E. Monroe, Shelbyville, spoke on appendicitis before the Shelby County Medical Society at Lithia Springs, recently.

Children's Clinics in Physicians' Offices.—School children of Springfield will receive free physical examinations and those unable to pay will be given treatment without charge, according to a plan adopted by the Sangamon County Medical Society, September 1. Vaccinations against smallpox and immunizations against diphtheria will be provided at reduced rates for families in moderate circumstances. The program was sponsored by Dr. Gottfried Koehler, who was recently appointed director of health and hygiene of Springfield schools, a position created with a view to instituting better health supervision in the schools. According to the plan, every doctor in the society will conduct a children's clinic in his office during one office period each week. The school health service will refer all cases to the family physician. The Sangamon-Menard-Logan County Dental Society is planning to adopt a similar program, it was reported. The dental examinations will be conducted at the schools instead of in the dentist's office. The plan will prevail only during the current economic depression.

Chicago

Dr. Curtis Goes to Ohio University.—Dr. George M. Curtis has resigned as professor of surgery in the Graduate School, Division of Biological Sciences, University of Chicago, to accept a similar position at Ohio State University College of Medicine, Columbus. Dr. Curtis became associated with the university in 1925, when he was appointed associate professor of surgery and associate professor of experimental surgery under the Douglas Smith Foundation for Medical Research at the institution. He will assume his new position at once.

Child Guidance Work.—Dr. Herbert E. Chamberlain has been appointed associate professor of psychiatry in the department of pediatrics, Division of Biological Sciences, University of Chicago. In this capacity he will assist in a study of delinquent children in Chicago. Medical cooperation covering the entire field of pediatrics will be provided for the study and it is planned to establish an adequate child guidance clinic to which children in need of psychiatric advice and treatment may be referred. While this clinic is being established to assist in this social service study, it is understood that patients from other sources will be accepted, particularly those referred by physicians in the department of pediatrics. It will be administered as a regularly constituted clinic under the jurisdiction of the department of pediatrics. Dr. Chamberlain recently resigned as director of the child guidance clinic of the board of education at Minneapolis.

INDIANA

License Reinstated.—At a meeting of the state board of medical examiners, July 14, the license of Dr. Pierre Lafayette Stewart, formerly of Fort Wayne, was reinstated on his "showing that he will engage in reputable practice." Dr. Stewart's license had been revoked, May 19, 1913, for his connection with a medical outfit that advertised.

IOWA

Graduate Courses.—The Speakers' Bureau of the Iowa State Medical Society will begin in Monticello, September 21, a series of graduate courses covering surgery in general practice, obstetrics and pediatrics. The fee is $15 for the combined courses, which will be held on Wednesday nights and run for ten weeks.

KANSAS

Personal.—Dr. Arthur J. Revell, Arma, became health officer of Cherokee County, September 1, succeeding Dr. Clarence R. Hepler, who has accepted a similar position in Sedgwick County.

The Old Settlers' Parade.—Dr. Solomon T. Shelly, Mulvane, now 76 years of age, held a reception on the lawn of his home, August 25, for all persons whose birth he attended during the past fifty years, 1,000 of whom attended. Dr. Shelly also rode the same day in the Old Settlers' Parade on a pony, the only means of travel during his first years at Mulvane.

MAINE

Health Department Wants Paralysis Serum.—The state department of health has made public a request for blood of persons who have had infantile paralysis not more than twenty years ago. Five dollars will be paid to each person responding to this appeal. The serum prepared from the blood given in this manner will be made available for all reported cases of infantile paralysis.

MARYLAND

Reorganization in Health Department.—R. S. Craig, director of the bureau of chemistry and food of the Baltimore health department, has been appointed director of the sanitary section, with supervision over all the sanitary activities of the department. This is a new position in accordance with plans for reorganization of the health department. F. A. Korff, now assistant head of the bureau of chemistry and food, will become director of that division. Later on, the announcement stated, the medical activities of the department will be coordinated under one head.

Reporting Occupational Diseases.—At a meeting of the state board of health, August 18, the board designated the Baltimore health department as its agent in receiving reports of cases of occupational disease within the city. Reports received by the city health department under the arrangement will be transmitted to the state board of health. The city health department plans to study conditions under which occupational diseases occur, for the purpose of assisting the industries in their prevention. In order to ascertain the extent of the problem, physicians in private practice or in hospital or dispensary service are requested to report industrial cases to the city health department on the postcards furnished for reporting communicable diseases.

Examination of Baltimore Children.—During the school year ended July 31, 9,123 children in public and parochial elementary schools in Baltimore were examined under supervision of the Baltimore County Health Department. Of these, 1,488 were underweight or gave other evidence of malnutrition; 7,703 needed dental attention, and 6,877 had infected or enlarged tonsils. Examinations in the public schools were made as a part of the regular activities of the health department, and those in the parochial schools on request. Analysis showed that the percentage of malnutrition was lowest in the first grades and gradually increased grade by grade, up to and including the sixth. Twenty-two child health conferences for the examination of preschool children were held in the county during the year; 722 children were examined. In this group 621 needed dental care; 421 had unfavorable conditions of the nose and throat and ninety-two were underweight. In both groups, 2,780 children were immunized against diphtheria and 998 had corrections made.

MASSACHUSETTS

Fall Graduate Courses.—A course of fifteen lectures and demonstrations on internal medicine for graduates in medicine will be given under the auspices of Harvard University Medical School by Dr. Frederick T. Lord, one each week, beginning September 21 and continuing through December 28. Each exercise will consist of the study of cases and an informal lecture. Subjects to be covered include diseases of the gastro-intestinal system, respiratory system, kidneys, blood-forming organs, the circulation, locomotor system, deficiency diseases, heart disease, syphilis, pneumonia, infantile paralysis and tuberculosis. The fee for the course, which will be given at Massachusetts General Hospital, will be $25.

MICHIGAN

Society News.—Dr. Salvatore Lojacono, superintendent of the Morgan Heights Sanatorium, Marquette, was elected president of the Michigan Sanatorium Association at its annual meeting, August 27, and Dr. Roger J. Hanna, Jackson, was elected secretary. The association will hold its next meeting in the Jackson County Sanatorium, Jackson.

Eyesight Swindlers Foiled.—That the "eyesight specialists" are again active in Michigan is indicated by a recent newspaper report. According to the account, two men, representing themselves as "eyesight specialists," called at the home of a farmer in Coe township. One conducted the examination, while the other remained outside in a car. After a lengthy examination, one of the children in the family proved to have a "cancer on the eye," according to the report, and the eyesight could be saved only by an operation in an "Eastern clinic." However, the "specialist" suddenly recalled that his waiting associate had developed a serum which would bring about results similar to those of the operation. The second "specialist" dropped the "serum" into the child's eye and removed a few minutes later what he said was the cancer. One of the men accompanied the farmer to the bank to receive the $875 which was charged for this "operation" However, the cashier regarded the withdrawal as rather large and after being informed of the circumstances called the police When the police arrived the "specialist" had left to find his associate.

NEVADA

Society News.—Dr. Ralph A. Reynolds, San Francisco, addressed the Washoe County Medical Society, June 14, on recent advances in endocrinology.

State Medical Meeting at Reno.—The twenty-ninth annual meeting of the Nevada State Medical Association will be held in Reno, September *23-24*, at the Hotel Golden, under the presidency of Dr. Amos C. Olmsted, Wells. Speakers announced in the program are:

Dr Miley B Wesson, San Francisco, "Infection in the Genito Urinary Tract"
Dr. Joseph P. Tuttle, Reno, "Prostatitis and Referred Pain"
Dr. James P Kerby, Salt Lake City, "Intravenous Pyelography"
Dr. Leo P Bell, Woodland, Calif, "Results of Operative Procedure on Stomach and Duodenum for Cure of Gastric and Duodenal Ulcers"
Dr James T Watkins, San Francisco, "Fractures of the Spine"
Dr William D Donoher, Salt Lake City, "Sinus Diseases"
Dr Charles A. Dukes, Oakland, Calif, "Treatment of So Called Inoperable or Incurable Cancers"
Dr Fuller B Bailey, Salt Lake City, "Functional Diseases of the Intestinal Tract"
Dr. Edgar L Gilcreest, San Francisco, "Undiagnosed Shoulder Lesions and Injuries"
Dr Martin A Robison, Reno, "Anesthetics"

Dr Olmsted will deliver the presidential address Friday morning at the opening session.

NEW JERSEY

New Division of Rockefeller Institute.—The department of plant pathology of Rockefeller Institute for Medical Research will start work about October 1 in its new laboratory now being completed at Princeton. Louis O. Kunkel, Ph D, who has been pathologist at the Boyce Thompson Institute for Plant Research at Yonkers, N Y., since 1923, is to be in charge of the new division (The Journal, June 20, 1931, p. 2131). The name of the entire Princeton section of the institute has been changed to the Department of Animal and Plant Pathology of the Rockefeller Institute for Medical Research. This is said to be the first time that the pathology of human beings, of plants and of animals has been studied in a single investigative unit.

NEW YORK

Personal.—Dr. Harry C. Hummell has been named deputy health officer of Rochester to succeed Dr. Arthur M. Johnson, who recently became health officer on the retirement of Dr. George W. Goler.

Hospital Celebration.—St. Mary's Hospital, Rochester, celebrated its seventy-fifth anniversary, September 8-10 The hospital was opened, Sept 8, 1857, by three Sisters of Charity. The present building, made necessary by an influx of wounded soldiers, was erected in 1862. In 1891 the interior was destroyed by fire, but it was immediately rebuilt. Since its establishment, the hospital is said to have cared for 137,726 patients, exclusive of outpatients.

New York City

Course in Psychoanalysis.—The New York Psychoanalytic Institute announces a series of ten lectures on psychoanalysis in medicine, to begin October 6 and continue for ten successive Thursdays. The lecturers will be:

Dr Clarence P Oberndorf, "History and Scope of Psychoanalysis" and "Psychopathology of Everyday Life—Mental Mechanisms"
Dr. Abraham A Brill, "Sexual Theory"
Dr Monroe A Meyer, "General Theory of the Neuroses"
Dr Dorian Feigenbaum, "Conversion Hysteria"
Dr. Alexander Sandor Lorand, "Anxiety Hysteria"
Dr. Philip R Lehrman, "The Compulsion Neurosis"
Dr Gregory Zilboorg, "Manic-Depressive Psychoses"
Dr Abraham Kardiner, "Schizophrenic Psychoses"

Registration may be made with Dr. Meyer at the institute, 324 West Eighty-Sixth Street. A fee of $10 will be charged.

The Fifth Annual Graduate Fortnight.—Following are the names of the speakers who will address the evening sessions of the Fifth Annual Graduate Fortnight of the New York Academy of Medicine, October 17-28.

Dr. Henry E Sigerist, Baltimore, "The History of Cancer"
Dr. Francis Carter Wood, New York, "Cancer Research"
Dr James Ewing, New York, "Factors Constituting Malignancy and Tumors"
Dr Harrison S Martland, Newark, N. J, "Consecutive Clinical and Pathological Events in Cancer"
Louis I Dublin, Ph D, New York, "Importance of Statistics in Cancer Control"
Dr Charles A Elsberg, New York, "Tumors of the Brain"
Dr Harvey Cushing, Boston, "Tumor of Optic Chiasm and Optic Tract"
Dr W Gordon M Byers, Montreal, Que, "Tumors of the Eye and Orbit"
Dr Samuel J. Kopetzky, New York, "Cholesteatoma"
Dr Byron P Stookey, New York, "Tumors of the Spinal Cord"
Dr Dean Lewis, Baltimore, "Tumors of the Nerves"
Drs George J Heuer and James Alexander Miller, New York, "Tumors of Pleura and Lungs"
Dr Edwin Beer, New York, "Tumors of the Bladder"
Dr Joseph F McCarthy, New York, "Malignancies of the Prostate"
Dr. George Gray Ward, Jr, New York, 'Cancer of the Uterus"
Dr Thomas S Cullen, Baltimore, "Fibroids and Adenomata"
Dr Benjamin P Watson, New York, "Tumors Complicating Pregnancy"
Dr Donald C Balfour, Rochester, Minn, "Cancer of the Stomach"
Dr. Daniel F Jones, Boston, "Tumors of the Colon and Rectum"
Dr Carl Eggers, New York, "Tumors of the Mouth and Tongue"
Drs James M Hitzrot and Ralph E Herendeen, New York, "Tumors of Bone and Allied Structures"
Dr Abernathy Benson Cannon, New York, "Tumors of the Skin and Mucous Membrane"
Dr Lloyd F Craver, New York, "Hodgkin's Disease and Lymphadenomata"

Afternoon clinical programs will be presented in eighteen leading New York hospitals. Concurrent with the fortnight and for a week thereafter, a scientific exhibit of approximately 3,000 units will be on view at the academy building. Demonstrations will be held at regular intervals in connection with some of these

OHIO

Fifth District Meeting.—The annual meeting of the Fifth Councilor District of the Ohio State Medical Association was held, September 16, in Cleveland Four addresses on pulmonary tuberculosis were presented by Cleveland physicians as follows Drs Joseph C Placak, diagnosis, Richard Dexter, diagnostic errors; Raymond C McKay, medical management; Samuel O Freedlander, surgical treatment Drs Henry J. Gerstenberger and Herbert S Reichle, Cleveland, presented a paper on tuberculosis in infancy and childhood Drs Marion A Blankenhorn and Robert H McDonald, Cleveland, spoke on neurologic manifestations and treatment, respectively, of pernicious anemia, Vernon C Rowland, on anemia of pregnancy, and Roscoe D Leas, treatment of secondary anemia. At an evening session held in conjunction with the Cleveland Academy of Medicine, Dr Gerald B Webb, Colorado Springs, Colo, was the guest speaker, on "Practical Points in the Diagnosis and Therapy of Pulmonary Tuberculosis" Dr Harry V. Paryzek is councilor for the district

PENNSYLVANIA

Society News.—The Second Councilor District of the Medical Society of the State of Pennsylvania held a meeting at the Reading Country Club, September 14 Dr Charles H Frazier, Philadelphia, spoke on "The Goiter Problem" and Dr. Walter F. Donaldson, Pittsburgh, on "The Renaissance of the Family Doctor." Dr. Charles Falkowsky, Jr, Scranton, president-elect of the state society, and Dr William H Mayer, Pittsburgh, president, made addresses, and Dr Mary E Lehman, Bristol, presented a brief history of the Bucks County Medical Society.

Philadelphia

Personal.—Dr. Abraham I. Rubenstone has been named medical director of Mount Sinai Hospital to succeed the late Dr. Henry B Shmookler. Dr. Rubenstone was attending physician at the hospital.

University News.—A sixty-bed addition to the building of the department of children's diseases of Temple University School of Medicine has been begun and twelve physicians have been added to the department staff, it was announced, September 2. The new appointees, who will assist Dr. Ralph M. Tyson, recently named professor of pediatrics, are Drs Henry H. Perlman, William H. Crawford, Edward D. Atlee, James E. Bowman, Scott P Verrei, Joseph Levitsky, Robert S. Heffner, Paul B Bender, Charles R. Barr, Vincent T. Curtin, Pascal F. Lucchesi and Samuel Goldberg.

SOUTH CAROLINA

Hospital News.—St Francis Hospital, formerly the Emma Moss Booth Memorial Hospital, Greenville, was opened for patients, July 18, by the Sisters of St. Francis. The building, which has a capacity of sixty beds, has been remodeled.

Society News.—The Abbeville County Medical Society was reorganized, August 12, at a meeting at the Abbeville County

Memorial Hospital Dr John V. Tate, Calhoun Falls, was elected president and Dr Francis L Mabry, Abbeville, secretary ——Dr Julius H Taylor, Columbia, addressed the Columbia Medical Society in July on "Treatment of Varicose Veins by the Injection Method"——Dr Lawrence H McCalla, Greenville, spoke on varicose veins and Dr Richard M Politzer, Greenville, on "Pitfalls of Pediatric Practice" before the Oconee County Medical Society at Walhalla, August 9.

VIRGINIA

Personal.—Dr Robert V Funston, Detroit, has been appointed professor of orthopedic surgery at the University of Virginia School of Medicine, succeeding Dr Allen F Voshell Dr Funston is a native of Virginia and a graduate of the university Before going to Detroit in 1922 he was associated with the department of orthopedic surgery at the University of Iowa School of Medicine——Dr Roy K Flannagan, assistant state health commissioner, has been detailed as medical adviser to the state department of public welfare——Dr Samuel T A Kent, Ingram, recently completed fifty years of practice in Halifax County

Illegal Practitioner Sentenced.—J E Gore, St Albans, W Va, is reported to have been fined $50 and costs and sentenced to six months in jail in Lexington after a hearing before Justice of the Peace Charles Cummings, August 11, on a charge of practicing medicine without a license The jail sentence was suspended on condition of good behavior for the next thirty years and until he should become qualified to practice medicine in Virginia It is said that Gore has for several years come into Rockbridge County at intervals to treat persons with cancer or supposed cancer with caustic pastes, collecting $100 or more in some cases In addition to paying the fine and costs, he was required to return $456 25 which he had collected from Lexington residents, according to the report

GENERAL

Outbreaks of Typhoid.—Two deaths are reported to have occurred in an outbreak of typhoid in a religious cult in De Kalb County, Ala It was said that when fifteen members of the cult became ill they refused medical aid until after the two had died——Ninety-three cases of typhoid have been reported in Philadelphia since January 1, in comparison with forty-nine in the same period of 1931——Summonses were served on 100 beach pedlers and 60 proprietors of stands at Coney Island, N Y, August 28, in a campaign against typhoid, which is said to be unusually prevalent in adjacent areas——An epidemic of paratyphoid has been reported from Clarion County, Pa, affecting about sixteen persons One death occurred, that of Dr Charles C Huston, Knox, who died August 8 The source of the infection had not been determined at that time

Radium-Active Company's Remedies Not Therapeutic.—The Federal Trade Commission has ordered Radium-Active Remedies Company, Pittsburgh, to stop representing that its products cure diseases or pathologic conditions of the human body or that they are radioactive unless they have radioactivity sufficient to give or add to the products a therapeutic effect when used in this capacity The commission found that the substance used as an ingredient which was claimed to be radioactive had in fact a radioactivity of less than 2 32 millimicrograms of radium a gram According to the commission, there is no therapeutic effect derived from the use of any medicament or medical appliance prescribed or used for the relief of disease or human ailments which has a radioactivity of this percentage None of the persons in charge of the company or employed by it were licensed practitioners in medicine, it was said Two of the officers who had been with the organization since 1928 were plumbers, one a high school teacher and one a chiropractor It was brought out that the company's medical adviser did not know how to measure the radioactive substance which was said to be an ingredient of its products, nor did he know its name or identity The commission held that the company's representations were calculated to mislead the public into buying its products for treatment of diseases in preference to products of competitors

Society News.—The nineteenth annual session of the International Association of Industrial Accident Boards and Commissions will be held in Columbus, Ohio, September 26-30 Medical questions to be discussed include "Common Hazards in Industry," Dr Emery R Hayhurst, Columbus, "What Determines Compensability of Skin Disease Among Industrial Workers," Dr Carey P McCord, Cincinnati, "The Traumatic Head Case," Dr Fred B Harrington, Weirton, W. Va, and "Functional Neuroses Their Nature and Relation to Injury," Dr George T. Harding, Jr, Columbus——J. P. Kobrzynski, D D S, Chicago, was elected president of the Polish Medical and Dental Association of America at the annual session in Wilkes-Barre, Pa, August 20 Drs Peter F Czwalinski and John A Czachorski, both of Chicago, were elected secretaries The next annual session will be held in Chicago in August, 1933——Dr Frederick C Warnshuis, Grand Rapids, Mich, was elected president of the Aero Medical Association at its annual meeting in Cleveland, September 4, and Dr Albert M Mitchell, Terre Haute, Ind, vice president ——Dr John P O'Connell, Chicago, was elected president of the International Association of Police and Fire Surgeons and Medical Directors of Civil Service Commissioners at its annual convention in Montreal, September 10 The 1933 session will be held in Chicago——The Frisco Railway Surgeons' Association will hold its annual meeting, November 14-15, in Memphis, Tenn——The American Academy of Physical Therapy will hold its annual meeting at the Hotel Walton, Philadelphia, October 12-14

Bequests and Donations.—The following bequests and donations have recently been announced.

National Jewish Hospital, Denver, $10,000 by the will of Mrs Jeannette D Beaumont

William Crispe Hospital, Plainwell, Mich, $35,000 by the will of Mrs Katherine Havens

Stanford University Medical School, San Francisco, $12,000 by the will of the late Dr Agnes Walker

Germantown Dispensary and Hospital, Philadelphia, $10,000 by the will of Mrs Katharine F Aschenbach, Germantown

Institute for the Crippled and Disabled, New York, $10,000, New York Infirmary for Women and Children, $500, and Babies' Hospital, New York, $2,500, by the will of Mrs Adele G Schiff

Vanderbilt University School of Medicine, Nashville, Tenn, $1 ‹00 for the purchase of radium, it is reported, by the heirs of the late Mrs. Leslie Warner

Passavant Memorial Hospital, Chicago, $25,000 by the will of Mrs. A P Chard

Children's Hospital, Columbus, Ohio, $1,000 by the will of the late Mrs Ella I Baker

Pennsylvania and Women's Homeopathic hospitals, Philadelphia, $10 000 each by the will of John T Morris who died in 1915 The bequests were held in trust until the death of his sister, which occurred in January

Flushing Hospital, Flushing L I, $10,000, and Trudeau Sanatorium, Trudeau, N Y, $5,000 by the will of the late Lomax Littlejohn

Christ Hospital, Jersey City, N J, $25,000, and Nassau Hospital, Mineola, N Y, $10,000 by the will of the late Mrs May Brady Harriman

Presbyterian Hospital, Chicago, $10,000 under the will of the late Martin A Ryerson

Lenox Hill Hospital $25 000, New York, and the United Hospital Fund, $10,000 under the will of Heinrich F F Sandhagen

Mansfield General Hospital, Mansfield, Ohio, $2,500 from the estate of the late Mary P Weldon

Presbyterian Hospital and Woman's Hospital, New York, $15,000 each Lincoln Hospital School for Nurses New York, Trudeau Sanatorium, Trudeau, N Y, $10,000 each under the will of the late Mrs Emma B Kennedy

Jewish Hospital, Brooklyn, $1,000 under the will of Mrs Pauline May

New York Society for the Relief of the Ruptured and Crippled, St Mark's Hospital, Lutheran Hospital, Stuyvesant Square Hospital and the Home for Incurables, all of New York, $9,015 each under the will of Mrs Amelia Walter

Presbyterian and University hospitals and Woman's Hospital of Philadelphia, $5,000 each under the will of Miss Margaret Dornan

Michael Reese and Mount Sinai hospitals, Chicago, $5,000 each by the will of Henry Friend

Report of United Fruit Company.—Malaria, influenza, venereal disease and injuries were the most frequent causes for hospitalization among the 73,251 employees of the United Fruit Company and the 76,640 other persons dependent on the company for medical facilities, according to the twentieth annual report of the company's medical department During 1931, 22,782 patients were treated in the company's ten hospitals in Central and South America and Cuba There were 1,062 deaths The total death rate for employees was 8 88 per thousand, pneumonia was the cause of the largest number, 168 Of the hospital admissions, 4,918 were for malaria, 1,440 for influenza, 1,179 for venereal diseases and 1,400 for injuries inflicted by firearms, instruments and falls A strenuous campaign against malaria since 1926 has resulted in a decrease from 218 hospital admissions per thousand employees in that year to 79 in 1931 Ninety-one deaths were due to malaria in 1931 A total of 55,803 persons were examined in malaria surveys made during the year and the blood specimens of 7,713, or 13 8 per cent, were found to be positive Although influenza caused the second highest morbidity rate, the cases were distributed throughout the company's divisions and there was no actual epidemic The high incidence of injuries is partly ascribed to a revolution in Honduras, 61 of the 118 deaths from this cause occurred in the Truxillo division alone There were 224 cases of typhoid and paratyphoid, the greatest number being reported from Santa Marta, Colombia, where polluted water caused an epidemic of 82 cases with 19 deaths In addition to patients in hospitals, 373,699 treatments were administered at dispensaries and 12,793 persons received medical attention aboard steam-ships or in ports. The fact that two severe cases of infectious jaundice among a number of mild cases in Santa Marta, Colombia, late in 1930 bore a notable resemblance to yellow fever led to an investigation in cooperation with the Rockefeller Institute. Definite results have not been obtained and the investigation is still in progress. Dr. Roland C. Connor, New York, became manager of the medical department in 1931, succeeding Dr. William E. Deeks, who died, July 24, 1931.

Government Services

Army Personals

Major Henry W. Meisch, relieved at Fort McPherson, Georgia, and assigned at Chilkoot Barracks, Alaska; Major Josiah B. Henneberger, relieved at Madison Barracks, New York, and assigned for duty in the Panama Canal Department; Major Joseph C. Breitling, relieved at Chilkoot Barracks, Alaska, and assigned at Fort Missoula, Montana; Major Baxter R. Hunter, on completion of present tour of foreign service, is assigned at Fort Howard, Maryland; Col. Thomas S. Bratton, having attained the age of 64 years, August 10, his retirement from active service is announced; Major Fielding T. Robeson, Fort Slocum, New York, has proceeded to his home to await retirement, for the convenience of the government; Col. Herbert C. Gibner, relieved at Letterman General Hospital, San Francisco, and assigned in the Hawaiian Department; Major Charles G. Sinclair, relieved at New York and assigned in Hawaiian Department.

U. S. Public Health Service

Passed Asst. Surg. Homer L. Skinner, relieved at Savannah, Ga., and assigned at U. S. Marine Hospital, New Orleans; Asst. Surg. Russell Thomas, relieved at Boston and assigned at U. S. Penitentiary, Lewisburg, Pa.; Asst. Surg. Mason V. Hargett, relieved at Washington, D. C., and assigned at marine hospital, New York; Asst. Surg. Robert S. Baylor, Jr., relieved at New York and assigned to the marine hospital, Cleveland; Passed Asst. Surg. G. G. Holdt, relieved at Ellis Island, N. Y., and assigned at Toronto, Canada; Senior Surg. Grover A. Kempf, relieved at Vienna, Austria, about September 1, and assigned to duty in office of American Consul, Berlin, Germany; Senior Surg. George Parcher, relieved at Warsaw, Poland, about September 10, and assigned at the U. S. Marine Hospital, Stapleton, N. Y.; Surg. Peter J. Gorman, relieved at Glasgow, Scotland, about September 1, and assigned at the American Consulate, Hamburg, Germany; Passed Asst. Surg. Paul A. Neal, Jr., relieved at Palermo, Italy, about September 1, and assigned at the American Consulate, Naples; Surg. John M. Lowrey, relieved at Naples, Italy, about October 1, and assigned at the U. S. Marine Hospital, Baltimore; Surg. Herbert M. Manning, relieved at Stuttgart, Germany, September 1, and assigned at the American Consulate, Warsaw, Poland; Passed Asst. Surg. Maurice A. Roe, relieved at Hamilton, Canada, September 1, and assigned at Yarmouth, Nova Scotia. The following persons were recently promoted and commissioned as surgeons in the regular corps of the public health service: Walter G. Nelson, Calvin C. Applewhite, Roy E. Bodet, Frank V. Meriwether and Albert E. Russell.

Change of Station in the Navy

Lieut. Cecil L. Andrews from navy hospital, Boston, to navy station, Guam; Comdr. Clarence W. Ross from navy hospital, Pearl Harbor, T. H., to navy hospital, Mare Island, Calif.; Lieut. John M. Woodard from navy station, Guam, to navy hospital, Mare Island, Calif.; Lieut. Comdr. Edward L. McDermott from submarine base, Coco Solo, C. Z., to navy hospital, League Island, Philadelphia; Lieut. Thenton D. Boaz from marine barracks, Quantico, Va., to the Asiatic Station; Lieut. Bruce E. Bradley from the naval hospital, New York, to the Asiatic Station; Lieut. John N. C. Gordon from the Norfolk Naval Hospital, Portsmouth, Va., to the Asiatic Station; Lieut. Robert D. Crawford, Jr., from the navy yard, Washington, D. C., to the Asiatic Station; Lieut. Gerard B. Creagh from the naval hospital, Parris Island, S. C., to the Asiatic Station; Lieut. Comdr. Morton D. Willcutts from the naval training station, Great Lakes, Ill., to the marine detachment, Peiping, China; Lieut. Charles V. Hatchette has submitted his resignation, effective November 30.

Foreign Letters

LONDON

(From Our Regular Correspondent)

Aug. 27, 1932.

Poisoning by Yew Tree Leaves

An inmate of Maudsley Hospital met his death in a manner which was new to the authorities. He was an insurance company secretary, aged 26, who was admitted as a voluntary patient for a nervous breakdown. On the lawn in front of the veranda where he slept was a yew tree, and a considerable quantity of the leaves were found in his alimentary canal. At the inquest Dr. Creed, pathologist, said that the man's normal behavior, the fact that he had a meal before his collapse, suggested that he was not aware of the danger of yew tree leaves, which might not be unpleasant to the palate. The quantity found in his stomach was not consistent with casual chewing. Dr. Tennent, deputy medical superintendent of Maudsley Hospital, asked by the coroner why the big tree was not removed, replied that he did not know that it was a yew tree. He knew the yew tree as a shrub but was not aware that it grew to such a size. If he had known, he would have had it cut down. None of the medical staff knew that it was a yew tree. Evidence was given that the man was cultivating the habit of chewing leaves to supersede the habit of smoking, which he had told his wife he would give up. The coroner said that it was a most unusual case. The man was getting better and wrote cheerful letters to his wife. It did not seem that he intended to commit suicide. The jury returned a verdict of accidental death with a rider to the effect that all bushes, shrubs and trees like the yew should be removed from grounds to which mental patients had access.

A second death has occurred in London within a fortnight from an insane person eating yew leaves. The second death was of a woman, aged 63, at the Springfield Mental Hospital, Tooting. The assistant medical officer stated at the inquest that yew trees had been in the grounds over thirty years but had now been destroyed. The jury expressed the opinion that yew trees and other poisonous plants should be removed from hospitals to which mental patients have access. It is strange that while the danger of mental patients eating yew leaves has been long pointed out in works on toxicology, these London institutions should have permitted them to grow in their grounds.

The Action of Rays on the Skin

Sir Leonard Hill, the physiologist, has made the curious observation that the prickly sort of heat felt on facing an electric fire is notably relieved on bringing close to the face an incandescent lamp screened by a sheet of glass. The one set of rays antagonizes the action of the other on the skin. The effect is not observed if a sheet of gelatin or cellophane is used as a screen. He also finds that the rays from an electric fire or dark source of heat, by acting on the skin reflexly, cause congestion of the nose and a feeling of stuffiness in those who have a deflected septum and some nasal obstruction. Those with unobstructed noses may be made sensitive by obstruction produced by a nose clip. The rays from an incandescent lamp also counteract these "nose closing" rays, and in this case the counteracting rays may act on a part of the skin other than that irradiated by the electric fire. Cooling the face prevents the nose closing effect. Hence the importance of ventilation of rooms with cool air. The skin when wet from perspiration is protected from the "nose closing" rays, and the vapor arising from a bowl of water set in front of an electric fire has the same protective influence. Glass absorbs most of the "nose closing" rays and lets the "nose opening" ones through. The latter belong to a group between about 20,000 and 30,000 angstroms, in the region of the short infra-red rays. Such sources of heat as the open fire or modern gas fire are pleasant because they give off enough of those beneficent rays.

The Biology of Human Nature

In a lecture on the biology of human nature, delivered at the recent meeting of the British Medical Association, Prof. Julian Huxley showed his power once again as an original thinker. He emphasized the importance of man's variability as a species. Nature tended to an enormous multiplication of species with little variation within each, but in human evolution two factors had operated to produce a result quite different from elsewhere —mass migration, which kept on bringing the variants into contact, and the fact that tradition more than structure or instinct regulated human behavior. As a result of constant migration, the divergent groups of men had never succeeded in becoming isolated physiologically. By virtue of interbreeding between migrant members, single groups came to throw up a much greater range of types, owing to Mendel's law, than would a wild species, and this produced further curious consequences. It meant that there must always remain a residuum of incomprehensibility between different members of society. The tough-minded could never really understand the tender-minded; the moron could never appreciate the philosopher, or vice versa. With a mind impelling him toward unity, political and social, man could not help generating diversity.

The Complex Origin of Hematemesis

Addressing the Société des médecins des hôpitaux de Paris, Messieurs René A. Gutmann and Michel Demole reported the results of the examination of 100 patients sent to the hospital on account of hematemesis. To simplify matters, they eliminated the cases of melena. Among the hundred patients, the authors found only nineteen cases of stomach ulcer and three cases of cancer of the stomach. Hematemesis in patients with appendicitis or cholecystitis, with or without perivisceritis, is well known, and the authors emphasize its frequency. In six cases they found mild hepatic conditions, alcoholic cirrhosis and hepatic syphilis. After the elimination of a number of rare causes, such as benign tumors and gastric syphilis, there remained twenty-one cases in which no research and no exploration enabled them to establish a diagnosis; these were possibly connected with blood disorders, of vascular or splenic origin, and all little known. These cases show that one should not, in the presence of a hemorrhage of digestive origin, think solely, as is usually the case, of an ulcer or a cancer. The statistics direct attention to hemorrhages due to secondary gastric disorders (appendicitis, cholecystitis), and emphasize the importance, in the genesis of hemorrhages, of dyscrasic factors as yet but imperfectly understood.

Diaphoresis Induced by Pilocarpine in the Treatment of Influenza

Before the Société des médecins des hôpitaux de Paris, an address of Dr. Monnerot-Dumaine was presented by Dr. Jean Troisier, which tends to restore to honor the use of diaphoresis in the treatment of various infections, a practice among the laity, the traditions of which date back to the time of Hippocrates. The practice survived for many centuries in ancient medicine, taking on the form of administration of copious hot decoctions and the wrapping of the patient in heavy woolen blankets. It is still in vogue among many primitive peoples as a means of combating intoxication, poisonous stings, and the like. Monnerot-Dumaine endeavored to use a more scientific method by resorting to hypodermic injections of pilocarpine salts. The effects, he states, were remarkable in the treatment of influenza. A simple uncomplicated inflenza at the start, even though associated with fever, usually yields to the heavy perspiration brought about by the injection of pilocarpine hydrochloride. Influenza that is well advanced, and even associated with some bronchitis, often clears up within twenty-four hours following such an injection. If the pilocarpine does not induce a heavy perspiration, the influenza is not at all affected. In that case, heavier doses of the alkaloid should be tried. The results and the mode of utilizing this method in complicated influenza, infantile influenza and influenza in the aged remain to be determined. If the favorable influence of the diaphoresis induced in influenza is confirmed, the author suggests that the method might be extended to other infections. These observations are interesting, but one must not forget that pilocarpine is not merely a sudorific and salivatory agent but affects also the sympathetic nerve and has a complex action on the heart and the lungs, for which reasons it must be administered with extreme care. But these facts do not detract from the therapeutic value of the induced diaphoresis, which has probably been unjustly discarded.

Personal

Mr. Edward Tuck, an American citizen, has been accorded the title (only rarely bestowed) of "honorary citizen of Paris," awarded by the municipal council of the capital. Having settled many years ago in France with his wife, he has never ceased —aided by his wife—to give evidence in many ways of his attachment for the country of his adoption. He has spent lavishly his large fortune in philanthropic works. He created at Rueil, near Paris, during the war, a large admirably equipped hospital, which has become, since the war, an old people's home, which is supported entirely at his expense. A magnificent art collection that he had spent many years in assembling he presented, on the death of his wife, to the city of Paris. It occupies several rooms of the Petit-Palais, on the Champs Elysées. Mr. Tuck had already been accorded the highest rank in the Legion of Honor, and was the holder of the "grande médaille d'or" of the city of Paris.

Mr. George Blumenthal, a citizen of the United States, has been awarded the title of Grand Officer of the Legion of Honor. This distinction, rarely accorded to foreigners, is in recognition of the many philanthropic works carried out in favor of France by Mr. Blumenthal and his wife, Florine Blumenthal, and particularly the construction of modern pavilions in the hôpitaux de Paris, for which he has expended large sums.

Deaths

At the Academy of Medicine, the death of W. W. Keen of Philadelphia, who was a foreign associate member of this society, was officially announced, and a short sketch of his life and works was presented by Professor Hartmann.

Dr. Charles Abadie has died at the age of 90. He was the Nestor of the French ophthalmologists. Reared in Bordeaux, he became, in 1868, intern in the hôpitaux de Paris and thereafter soon acquired for himself a preeminent position in his chosen specialty. He published numerous works, the most important of which dealt with trachoma, glaucoma, the various forms of atrophy of the optic nerve, and the like. He was the first to employ to a wide extent in France, in spite of the opposition of the syphilologists, intravenous injections of mercuric cyanide in numerous diseases of the eye. Having an active mind and a wide literary culture, he preserved in his extreme old age the use of his intellectual powers and his working energy. Only two years ago, he presented, before the Academy of Medicine, a remarkable communication on the medical treatment of glaucoma.

Dermatitis from Wrist Watch

In the *Annales de dermatologie*, Dr. Dubois calls attention to two peculiar cases of dermatitis caused in women by the wearing of wrist watches. Both patients observed a roundish red spot of regular appearance about the size of the wrist watch, and located at the point of application of the watch. In one of the women, the eruptive manifestation was more acute. An erythematous, squamous disk, roundish and somewhat infiltrated, could be observed. The surface, which was oozing slightly, was dotted with small, clear vesicles and crusts. The lesion yielded in three weeks to treatment with calming pastes. The cause of the dermatitis was an idiosyncrasy toward nickel, a thin coating of which covered the steel case of the watch. Such instances are rare, when it is considered what a large number of women wear such watches, which originated in Geneva. Moreover, the parents and two sisters of one of the patients wore these watches without any inconvenience. The lesions in the cases cited appeared about a week after the watches were first put on. To verify the diagnosis, a nickel twenty-five centime piece was fastened to the wrist; a week later, the cutaneous reaction appeared.

Expenditures for Food and Luxuries in the Families of Workmen

In a work recently published by the Federal Bureau of Statistics, "Die Lebenshaltung von 2,000 Arbeiter-, Angestellten- und Beamtenhaushaltungen," will be found highly interesting and valuable researches for the estimation of the financial condition of workmen, employees and petty officials in Germany. These statistics cover the period from March 1, 1927, to Feb. 29, 1928, and comprise records of 2,000 families (896 workmen, 546 employees and 498 petty officials) that kept careful records of their receipts and expenditures according to a definite questionnaire. The selection of the families was made in such a manner that the various sections of the *reich,* and the most important industrial groups and occupations, were represented. The large cities were given preference (80 to 87 per cent); the cities of middle size came next (12 to 20 per cent), while only a few small towns were represented.

Only married persons were considered. The average number of children (under 15 years of age) grows with the income in all three groups and does not become lower other than in the uppermost ranges (among employees and officials), which may be easily explained by the differences in the ages of the persons concerned. Moreover, in the families of the workmen the numbers are greater than in the families of the employees and of the officials, although the differences are not very marked, for the number in the families of workmen, employees and officials ran as follows: 4, 3.6 and 3.8, respectively.

On studying the incomes of the three groups in relation to the expenditures, it was found that the average annual income of the workmen was $863.25, $1,121.46 for the employees, and $1,273.30 for the officials. A comparison of the use of income in the three groups, divided according to the amount of income into five grades, reveals that in all groups the expenditures for food head the list, being proportionally highest among the workmen, in whose case they amount to 42 per cent of the total expenditures in the lowest income class, and with rising income drop comparatively rapidly, so that in the group of workmen with the largest income they amount to only 35.7 per cent, whereas in the case of employees and officials with still larger incomes they decline to 27.5 per cent.

The average protein consumption rises from the lowest to the highest income class (in all three groups) about 20 per cent, chiefly owing to the increase in the consumption of animal foods, whereas the consumption of vegetable protein is about the same in all three groups—or may be less among the officials. On an average, more animal protein than vegetable protein is consumed, which complies with physiologic demands. Also the total daily consumption of protein is in general satisfactory. Only in the two lowest income classes of the workmen does the protein consumption possibly fall below the minimum requirements. Likewise the number of calories demanded by the physiologist appears to be fully reached, among the employees and officials, by the amount of food ingested, whereas in the lowest income classes of the workmen there is a slight deficit. The expenditures for luxury articles of consumption, especially alcoholic beverages, appear rather high. The amounts expended per family run as follows: among the workmen, 104 liters of beer, 1.8 liters of brandy, 8.5 liters of wine, the annual cost of which was $20.08; among the employees, 77 liters of beer, 2.5 liters of brandy, 10.5 liters of wine, the annual cost of which was $20.07; among the officials, 79.5 liters of beer, 2.4 liters of brandy, 12.7 liters of wine, the annual cost of which was $21.61. In point of fact, the average consumption of alcoholic beverages in Germany for the aforementioned period was considerably larger, as is expressly emphasized in the statistics. It may be assumed, therefore, that the families considered in this scrutiny were more abstemious than the average. In any event, the consumption of alcoholic beverages was rather large, whereas the expenditures for "education" were considerably less than for alcoholic beverages and tobacco.

The Requirements for Recognition as a Specialist

It is only natural that, with the perfection of diagnostic and therapeutic methods and the recognition of special branches of medicine, physicians should devote themselves to certain specialties. At first there was the differentiation "general practitioner," "surgeon" and "obstetrician." Further differentiation brought the ophthalmologist, the laryngologist, the rhinologist, the otologist, the gynecologist, the dermatologist, and many others. Many of the early specialists acquired the right to be regarded as such by virtue of special talent widely demonstrated in a certain field of medicine. They had been general practitioners, but, on discovering their talent and liking for a more restricted practice, they had devoted themselves more and more to that practice and with such success that they decided to confine themselves entirely to that field. At a later period, many claimed the right of announcing themselves as specialists by reason of having served for varying lengths of time as assistant to a well known and recognized specialist in a given branch of medicine. Still later, patients made the acquaintance of the so-called six weeks specialists, who had taken a short course somewhere and then sought out a location as "specialist." In view of these loose conditions, the medical profession of Germany launched, a number of years ago, a campaign to bring about that no physician be permitted to announce himself as a specialist in a given branch of medicine until he had demonstrated that he actually possessed special ability in that field. At first, however, no suitable way of demonstrating the possession of special ability in a chosen field was discovered. Neither the medical profession nor the governmental authorities took kindly to the suggestion that would-be specialists be required to subject themselves to a special examination, which if successfully passed would entitle them to a specialist's diploma and would authorize them to practice their chosen specialty. On the other hand, the medical profession proposed and adopted a set of criteria or regulations on the basis of which German physicians might recognize a colleague as a specialist, and which provided further that the term "specialist" should be restricted to definitely recognized branches of medicine. These criteria have been revised and amplified, and, as they now stand, they state the varying periods of time that are considered the minimum necessary for training in the various specialties and what kind of special training appears suitable. On the basis of documentary evidence submitted, the local medical organization decides whether a petition for recognition as a specialist in a given branch of medicine shall be approved. In case the petition of an applicant is rejected, he may take a final appeal to the "chamber physicians" (*aerztekammer*) having jurisdiction in the region in question.

It took some time before the new procedure for the recognition of specialists was accepted and put into practice by the medical organizations, but it may be vehemently declared that, the more consistently it has been applied, the more feasible it has been proved to be. According to the regulations governing at present the admission of panel physicians to practice in the *krankenkassen*, or health benefit associations, no specialist will be recognized who has not been approved by a competent medical organization.

The following specialties have been definitely recognized as such: surgery, diseases of women and obstetrics, orthopedics, diseases of the eye; diseases of the throat, nose and ear; diseases of the skin and genital diseases, urology, nervous and mental diseases, roentgenology and light therapy; diseases of the teeth, jaws and mouth (in addition, license as dentist required); internal medicine (including nervous diseases), diseases of the stomach and intestine and disorders of metabolism (disorders of the respiratory tracts), and children's diseases (only children under 14 years of age; treatment [including consultations] of adults is positively prohibited). These specialists must confine themselves, in the main, to their specialty and to consultative office hours and institutional service; that is to say, they may make house calls only in emergencies and must avoid anything like the ordinary domiciliary practice of the general practitioner.

The period of special training required of applicants for admission as "specialist" varies with the specialty, being at least four years for surgery, gynecology, obstetrics and internal medicine, and three years for the remaining branches. The announcing of oneself as a specialist in more than one branch or for branches other than those named will not usually be permitted; exceptions are, for example, surgery and orthopedics, surgery and gynecology, if the preliminary training is adequate, covering at least six years. It may be said now, after the regulations have been in operation for a few years, that these criteria have proved their value and have clarified to a great extent a previously bad situation.

Vaccination Against Yellow Fever

Dr. H. de Beaurepaire Aragão, head of the Instituto Oswaldo Cruz, recently published an article on the prevention of yellow fever by means of immunizing vaccines. Although the problem has been discussed ever since the time of Pasteur, it was not until recently that it was more clearly understood and later made practical. In the first attempts at immunization, the vaccines were prepared by killing the yellow fever virus (present in the organs of Macacus rhesus previously infected with yellow fever) with solution of formaldehyde. Later, chloroform, glycerin and phenol (carbolic acid) were used, instead of formaldehyde, as agents to kill the virus, without impairing its immunizing properties. But the immunity conferred by the formaldehyde vaccines was not lasting. In a review of the entire problem, it was found that the failure of the vaccines to lead to the development of antibodies was due to the use of a killed virus in the preparation of the vaccine and that, by preparing the vaccines either with a living virus of an attenuated virulence or with a virus previously neutralized by a certain technic, lasting immunity is obtained. Immune serum (that is, the blood serum of men who have had yellow fever or of a Macacus rhesus monkey that survived an experimental infection) has a protective action which prevents the development of the disease, as proved by the lack of any reaction in normal men or monkeys that are given an injection of yellow fever virus after a previous injection of immune serum. De Beaurepaire Aragão succeeded in obtaining lasting immunity in Macacus rhesus by the inoculation of 2 cc. of blood serum of either convalescents or monkeys that had been immunized by the injection of 1 cc. of blood which contained yellow fever virus of great potency. The animals that received the injection did not show any general or local serious reactions, either after the immunizing vaccine or later, when a new injection of 0.1 cc. of yellow fever virus was given to them. The immunity thus conferred proved to be present even six months later. The same satisfactory results were obtained when the technic was slightly modified, by making the two injections (that of immune serum and that of virus) simultaneously, thus shortening the time of the procedure. Shortly after the method of the vaccination was reported, several laboratories in which yellow fever work is done confirmed its value. Findlay and Hindle reported their results in Macacus rhesus (*Brit. M. J.* **1**:740 [May 2] 1931; abstr. The Journal, July 18, 1931, p. 210). Shortly after, Sawyer, Kitchen and Lloyd reported satisfactory results in vaccinating human beings against yellow fever with immune serum and virus fixed in mice (*Proc. Soc. Exper. Biol. & Med.* **29**:62 [Oct.] 1931). Immunization was obtained in ten persons by the injection of a mixture of immune serum and living virus, after a previous injection of serum from convalescents. The blood serum from those persons acquired the power to protect Macacus rhesus against yellow fever, thus proving the acquired immunity of the individuals. Sellards and Laigret reported satisfactory results in vaccinating five persons (*Compt. rend. Acad. d. Sc.*, May 2, 1932). The authors injected the persons to be immunized with a living virus of yellow fever, fixed for mice only. It has been proved that the virus provokes an infection of an attenuated virulence in Macacus rhesus and probably also in man (although one should remember that three instances have been reported of benign but typical yellow fever infections of laboratory origin through the virus in white mice). The basic principle of the vaccination is the use of a living virus. Up to the present, there have been four methods of vaccination, the results of which should be compared so as to choose the one that may give the best results.

Coexistence of Vincent's Angina and Diphtheria

Dr. Mangabeira Albernaz recently read a paper before the Sociedade de Medicina e Cirurgia of the city of Campinas in the state of São Paulo, on the coexistence of Vincent's angina and diphtheritic angina, which is rare. The author warns against confusing the association of these two forms of angina with those cases in which one form only is present but in which the etiologic agents of both forms are present. The speaker believes that the clinical diagnosis is more important than the microscopic diagnosis. The microscopic diagnosis is of great value as a confirmation of the results of the clinical diagnosis. If the angina improves under the effect of the serum or of local bismuth treatment, this proves that there is not a true association of the two forms of angina even though the examination has shown the presence of the etiologic agents of both forms. That is the reason why the benign ambulatory forms of both diphtheria and fusospirochetosis are spontaneously cured. The only thing that proves the simultaneous existence of the two diseases is the presence of the different types of false membranes. The membranes in diphtheria are continuous, pale yellow, adherent and with loose lateral edges. The membrane in fusospirochetosis is dark, is fragile, and exists only for a short period of the disease. In cases in which the coexistence of the disease is well proved, the treatment must be mixed: serum in large amounts and local bismuth treatment. The treatment gives good results because in cases in which the two diseases coexist there is a reciprocal action of the virulence of the two etiologic agents. The author reports three cases in which both diseases were present and in which the diagnosis was made by the clinical examination and confirmed by the laboratory tests.

CAPE TOWN

(From Our Regular Correspondent)

July 29, 1932.

The Medical Congress

The twenty-sixth South African Medical Congress was held last month at East London. Although the attendance was small, largely owing to the fact that so many medical men who can afford to leave their practice have gone overseas to attend the centenary meeting of the British Medical Association in London, the meeting was one of the most successful held since the war. The opening address by Sir Carruthers Beattie, vice chancellor of the University of Cape Town, attracted considerable attention, dealing as it did with the much discussed topic of overcrowding of the profession and of the medical schools in this country. Sir Carruthers is of the opinion that South Africa should have many more physicians than it has at present. He pointed out that in some parts the proportion was one physician to fifty thousand patients, and that our annual wastage was at present not compensated for by our annual number of graduates, but that we still have to import medical men from abroad. The address has been much discussed, and it is safe to say that Sir Carruthers' view is not that held generally, the consensus being that, in both urban and rural areas, medical practice holds out so little that is attractive that new comers are to be discouraged. Some also think that the medical schools have reached the limit of their usefulness, as there is not enough clinical material. This argument is on the face of it absurd, for both Cape Town and Johannesburg have populations that are large enough to provide ample clinical material for teaching purposes provided it is properly organized. At present much of this material is wasted because it is not coordinated with the university classes, with the result that few students are aware of its value. At Cape Town, for example, much of the polyclinic work, which in continental centers is regarded as so valuable an adjunct in teaching, is in charge of specialists who do not teach and is rarely seen by the students. There is little doubt that Sir Carruthers' address has stimulated discussion and may lead to important developments in the near future. The Medical Association of South Africa has appointed a special committee to consider, generally, the medical curriculum and the provision made for medical teaching at our two universities, and this committee will be in close cooperation with the standing committee on insurance and medical practice.

Among the many interesting papers read at the congress was one read before the Section of Public Health by Dr. Laidler of East London. His subject was the interrelation between European and native ill health, and he showed how the neglect to provide adequate medical service for our native and Negro population reacts on the white community. The paper was remarkable for its careful and detailed analysis of vital statistics and for the broad generalizations that were made. It led to a vigorous discussion, the final result of which was that congress passed a resolution urging the government to take a native census, since without proper statistics it is impossible to arrive at any definite conclusions on many points of great importance.

THE MEDICAL ASSOCIATION OF SOUTH AFRICA

At the congress the Medical Association of South Africa held its triennial election of executive officers. Dr. Orenstein, who for six years has served as its president and who did not offer himself for reelection, retires in favor of the vice president, Dr. Sandes of Cape Town. Dr. Sandes is one of the senior surgical specialists in the union, a lecturer on surgery at the University of Cape Town, and an old member of the old South African Committee of the British Medical Association. In his place, as vice president, was elected Sir Spencer Lister, the director of the Medical Research Institute at Johannesburg, while on the executive committee are Sir Edward Thornton, Dr. Orenstein and Dr. Moffat of Cape Town.

THE NEW MEDICAL OFFICER OF HEALTH FOR THE UNION

The medical officer of health for the union, Dr. Mitchell, retired this year, and has been succeeded by the second in command at the department, Sir Edward Thornton. Sir Edward is an old public health officer who has had considerable experience with health work in the native territories. He did excellent service in the late war, organizing hospital services both here and in France; for his work at the front he received the honor of knighthood. On his return from active service he was appointed director of medical services to the union defense force, an important post which he has since held in conjunction with his official post as assistant medical officer of health for the union. In his new capacity as medical officer of health he is both chief public health official and the administrative head of his department, as he is also secretary of public health.

Eruptive Fevers of the Typhus Group

Considerable attention is being paid by Cape and Natal pathologists to certain types of fever that are becoming increasingly common. There is still much doubt as to what category these fevers should be grouped into, but it is generally agreed that they present points of close clinical similarity to typhus. Wicht of Cape Town and Ross of Rhodesia, who have both devoted considerable time and attention to the serologic study of these fevers, are of opinion that they closely approach the Mexican tabardillo in one group and the tsutsugamushi disease of Japan. Conor and Bruch described similar syndromes in Algeria, but in those days the Weil-Felix reaction was not known. In South Africa, similar types of fevers have been described since 1911. Clinically they closely resemble typhus, but before the development of the typical rash the patients do not present symptoms that are diagnostic of the condition, so that the three most characteristic features of the disease have to be carefully looked for. These are the primary ulcer, due to the bite of the vector, whatever it may be, the temperature chart curve, and the rash itself. The rash mimics that of measles; indeed, in children it is often mistaken for that disease, especially as it appears on the fourth day after the patient has shown signs of feverishness and malaise. It is present on the mucous membranes of the nose and mouth as well as on the skin. Treatment so far has been purely symptomatic. Ross and Wicht incline to the view that the disease is carried by fleas, but that opinion is not shared by some pathologists, who consider that this form of typhus is merely tick bite fever, such as is well known and has been frequently described. There seems no doubt, however, that the condition does present differences from ordinary tick bite fever and that in this country we have to do with three distinct forms of typhus, one carried by lice, one by ticks and a third by some parasite of the rat, most probably a flea.

Protein Shock in the Treatment of Dementia Paralytica

Laubscher of the Valkenburg Mental Hospital has studied the results of the treatment of dementia paralytica by protein shock, tryparsamide and tartro-quiniobine in a series of cases not specially selected. He contributes to the *South African Medical Journal* an interesting summary of his observations, together with the case histories. His study deals with fourteen cases. Eight were social recoveries. Three patients who died showed Herxheimer reactions after recovery. Five remained unimproved, one of whom died at the beginning of treatment, and one improved both mentally and physically. The shock treatment was in the form of 10 cc. of milk given intramuscularly, followed, six hours later, by 1 Gm. of tryparsamide in 5 cc. of distilled water injected intravenously.

Marriages

William Joseph Morginson, Wheeling, W. Va., to Miss Elizabeth Jane Eitzen of California, Mo., September 6.

Perk Lee Davis, Philadelphia, to Dr. Margaret Henderson Shumway of Bryn Mawr, Pa., September 4.

Harold Charles Lueth, Chicago, to Miss Elizabeth Adelaide Bullock of Oak Park, Ill., September 3.

Forrest Le Roy Stratton, Kilgore, Texas, to Miss Karna May Billberg of Nowata, Okla., September 2.

Elbert Lapsley Persons, Durham, N. C., to Miss Helen Hopkinson Coles of Summit, N. J., June 11.

Charles H. White, Fenton, Mich., to Miss Bess N. Knowles of Detroit, June 25.

W. L. Weber, Philadelphia, to Miss Anna Ruth Bialy of Collingswood, N. J., May 25.

Don Shelley Benson, Elm Grove, W. Va., to Miss Gwen Kirker of Wellsburg, June 2.

Edmund Ralph Carman, New Lenox, Ill., to Miss Elsa Friday of St. Louis, June 11.

Louis C. Barrette to Miss Muriel Bradford, both of Sacramento, Calif., August 15.

Walter A. Brussock to Miss Cheryl Miller, both of Milwaukee, September 1.

J. Frank Maurer, Brazil, Ind., to Miss Susan Delbrook of Indianapolis, July 20.

Jacob Pomerantz to Miss Mollie Orloff, both of Philadelphia, August 14.

Joseph W. Kelso, Oklahoma City, to Mrs. Elsie E. Carter, July 20.

Meyer Zeltzer, Erie, Pa., to Miss Esther Bergoon, recently.

Deaths

Theodore August Hoch, Northampton, Mass.; University of Michigan Medical School, Ann Arbor, 1900; member of the Massachusetts Medical Society, American Psychiatric Association and the New England Society of Psychiatry; assistant professor of psychiatry, Tufts College Medical School; medical superintendent of the Northampton State Hospital; aged 53; died, August 4, of hemorrhage due to duodenal ulcer.

Edwin Page Bledsoe, Sykesville, Md.; College of Physicians and Surgeons, Baltimore, 1905; served during the World War; superintendent of the Springfield State Hospital; formerly superintendent of the Arkansas State Hospital, Little Rock, and medical officer in charge of the U. S. Veterans' Hospital, North Chicago, Ill.; aged 51; died, August 11, in Baltimore.

Andrew Samuel Moorhead, Toronto, Ont., Canada; University of Toronto Faculty of Medicine, 1906; fellow of the American College of Surgeons; served with the Canadian army during the World War; at one time demonstrator in clinical surgery at his alma mater; formerly on the staffs of the Toronto General and the Wellesley Hospital; aged 55; died, July 31.

John Jacob Conzett, Auburn, N. Y.; Miami Medical College, Cincinnati, 1899; member of the Medical Society of the State of New York; veteran of the Spanish-American and World Wars; medical school inspector; aged 58; died, August 9, in the Auburn City Hospital, of empyema of the gallbladder, chronic hepatitis and paralytic ileus.

Harris L. Cookingham, Red Hook, N. Y.; Albany (N. Y.) Medical College, 1871; member of the Medical Society of the State of New York; past president of the Dutchess County Medical Society; formerly president of the school board, postmaster and health officer; aged 81; died, June 28, in a hospital at Rhinebeck.

Jacob J. Entz, Wichita, Kan.; Bennett College of Eclectic Medicine and Surgery, Chicago, 1886; at one time member and epidemiologist to the state board of health; for seven years health officer of Marion County; formerly on the staff of the State Hospital, Norton; aged 68; died, June 29.

Hugh Boyd, Scottsboro, Ala.; Memphis (Tenn.) Hospital Medical College, 1899; member of the Medical Association of the State of Alabama; past president of the Jackson County Medical Society; served during the World War; aged 51; died suddenly, August 6, of angina pectoris.

Joseph Frederick Terriberry, New York; Bellevue Hospital Medical College, New York, 1880; formerly on the staffs of the Hospital for the Ruptured and Crippled and the Manhattan Eye, Ear and Throat Hospital; aged 75; died, July 28, at his summer home in Canaan, Conn.

Charles Melvin Ericsson, Gowrie, Iowa; State University of Iowa College of Medicine, Iowa City, 1905; member of the Iowa State Medical Society; for many years member and president of the school board; aged 60; died, July 29, in the Lutheran Hospital, Fort Dodge.

***George Gordon Campbell**, Montreal, Que., Canada*; McGill University Faculty of Medicine, Montreal, 1889; formerly clinical professor of dermatology at his alma mater; for many years on the staff of the Montreal General Hospital; aged 68; died, June 26.

George S. Stone, Fort Myers, Fla.; University of Maryland School of Medicine, Baltimore, 1890; member of the Florida Medical Association; past president of the Lee County Medical Society; on the staff of the Lee Memorial Hospital; aged 63; died, June 1.

James Monroe Dampeer, Crystal Springs, Miss.; Medical Department of the Tulane University of Louisiana, New Orleans, 1892; member of the Mississippi State Medical Association; formerly member of the state board of health; aged 64; died, July 14.

Robert Eben Hearne, Paducah, Ky.; Vanderbilt University School of Medicine, Nashville, Tenn., 1901; member of the Kentucky State Medical Association; served during the World War; aged 56; died, July 28, of carcinoma of the liver.

Charles L. Scott, Sanford, N. C.; University of Maryland School of Medicine, Baltimore, 1897; member of the Medical Society of the State of North Carolina; served during the World War; aged 56; died, July 26, of sarcoma of the spine.

Everett J. Stewart Scofield ⊕ Danbury, Conn.; University of North Carolina School of Medicine, Chapel Hill, 1908; formerly health officer of Danbury; for fifteen years on the staff of the Danbury Hospital; aged 52; died, July 16.

Charles William Aitkin, Flemingsburg, Ky.; Medical College of Ohio, Cincinnati, 1880; member of the Kentucky State Medical Association; for many years bank president; aged 72; died, August 10, of streptococcic meningitis.

Eli Nichols ⊕ Wilmington, Del.; University of Pennsylvania School of Medicine, Philadelphia, 1915; on the staff of the Delaware Hospital; aged 43; died, July 25, in the Johns Hopkins Hospital, Baltimore, of chronic myocarditis.

William Morrison Robinson, Jersey City, N. J.; University of Georgia Medical Department, Augusta, 1908; on the staff of the Greenville Hospital; aged 47; died, May 27, in Danville, Va., of a self inflicted bullet wound.

John Hill Focht ⊕ Shamokin, Pa.; University of Pennsylvania School of Medicine, Philadelphia, 1921; formerly proprietor of a hospital bearing his name; aged 40; was found dead, August 9, of illuminating gas poisoning.

Edith Mackay Ross, Winnipeg, Manit., Canada; Manitoba Medical College, 1913; member of the Associated Anesthetists of the United States and Canada; on the staff of St. Boniface (Manit.) Hospital; aged 43; died, May 13.

Marcus Bradford Carleton, Wooster, Ohio; Medical Department of the University of the City of New York, 1881; for many years a medical missionary in India; aged 76; died, July 24, in Xenia, of heart disease.

Henry Adams Waldron ⊕ Newburgh, N. Y.; Albany Medical College, 1877; aged 77; on the staff of St. Luke's Hospital, where he died, August 1, as the result of injuries received in an automobile accident.

Charles Carlisle Conser ⊕ Baltimore; University of Maryland School of Medicine, Baltimore, 1900; associate professor of physiology at his alma mater; aged 56; died suddenly, August 6, of heart disease.

Oliver Brewster Babcock, Springfield, Ill.; St. Louis Medical College, 1879; aged 75; died, August 6, in the Decatur-Macon Hospital, Decatur, of heart disease, pulmonary edema and cerebral hemorrhage.

Ernest H. Madajesky, Ironwood, Mich.; College of Physicians and Surgeons, Chicago, 1899; member of the Michigan State Medical Society; formerly a druggist; aged 61; died, July 20, of cerebral hemorrhage.

Rollin Guy Hendricks, Indianapolis; Central College of Physicians and Surgeons, Indianapolis, 1903; on the staff of the Indianapolis City Hospital; aged 54; died, July 24, of hypernephroma of the right kidney.

John Morgan Holloway, Jersey City, N. J.; New York Homeopathic Medical College and Hospital, 1893; member of the Medical Society of New Jersey; aged 63; died, July 31, in Sparta; of heart disease.

Frank Robert Maxwell, Martinsville, Ind.; Medical College of Indiana, Indianapolis, 1895; served during the World War; aged 60; died, July 10, in St. Vincent's Hospital, Indianapolis, of heart disease.

Lucius L. Ball, Muncie, Ind.; University of Buffalo School of Medicine, 1889; member of the Indiana State Medical Association; aged 82; died, July 22, of chronic urinary sepsis and prostatic hypertrophy.

Elmer P. Blankenship, Houston, Mo.; St. Louis University School of Medicine, 1909; also a druggist; served during the World War; aged 56; died, July 10, of uremia and cirrhosis of the liver.

Silas O. Kimbro, Monticello, Ark.; University of Nashville (Tenn.) Medical Department, 1906; member of the Arkansas Medical Society; aged 52; was found dead in his office, July 17, of heart disease.

Alden Edwards Martin, Hackettstown, N. J.; Hahnemann Medical College of Philadelphia, 1876; at one time mayor; formerly member of the board of health; aged 84; died, July 7, of myocarditis.

George R. Christian, Indianapolis; Medical College of Indiana, Indianapolis, 1897; member of the Florida Medical Association; aged 62; died, August 9, in St. Vincent's Hospital, of heart block.

Frank Pierce Johnson, St. Louis; Cleveland Medical College, 1877; member of the Missouri State Medical Association; aged 81; died, July 19, in the St. Louis County Hospital, of heart disease.

Zolley B. Ferrell, Parkersburg, W. Va.; Chicago College of Medicine and Surgery, 1916; aged 48; died, April 9, in the City Hospital of embolism, following an operation on the gallbladder.

Jean Henriette Celce, Holyoke, Mass.; Woman's Medical College of Pennsylvania, Philadelphia, 1892; member of the Massachusetts Medical Society; aged 62; died, July 30, of septicemia.

Samuel H. Blakely, Severance, Kan.; Louisville (Ky.) Medical College, 1875; also a druggist; aged 82; died, July 23, in the Methodist Episcopal Home for the Aged, Topeka, of senility.

John Frederick Shrontz, Martinsburg, Ohio; Physio-Medical Institute, Cincinnati, 1877; formerly member of the county school board; aged 82; died, July 26, of cerebral hemorrhage.

John H. Carson, Vancouver, B. C., Canada; Medical College of Indiana, Indianapolis, 1892; aged 70; superintendent of the Provincial Home for Incurables, where he died, May 17.

Patrick John Kelly, Patton, Pa.; Medico-Chirurgical College of Philadelphia, 1912; member of the Medical Society of the State of Pennsylvania; aged 56; died, July 23, of pneumonia.

Frank Lisle Rose, Brooklyn, Mich.; University of Michigan Medical School, Ann Arbor, 1886; formerly health officer of Saginaw County; aged 74; died, July 15, of heart disease.

Harry Francis Bailey, Monongahela, Pa.; University of Pennsylvania School of Medicine, Philadelphia, 1912; served during the World War; aged 46; died, July 14, of pneumonia.

Leland Carson McIntosh, Henderson, N. C.; Atlanta College of Physicians and Surgeons, 1913; served during the World War; aged 53; died, July 14, of chronic encephalitis.

George Leo Helms, Los Angeles; Medical Department of the University of California, 1895; aged 60; died, June 8, in the Stockton (Calif.) State Hospital, of cerebral hemorrhage.

Joseph Brewer Blades ⊕ Independence, Kan.; Kansas City Medical College, 1905; on the staff of the Mercy Hospital; aged 56; died, July 25, in Madison, Wis., of arteriosclerosis.

Frederick Carlyle Hyatt, Greensboro, N. C.; Jefferson Medical College of Philadelphia, 1907; aged 47; died, July 28, at Waynesville, of cardiovascular renal disease.

Joseph M. Hartranft, Southold, N. Y.; Hahnemann Medical College of Philadelphia, 1879; formerly health officer of Southold; aged 74; hanged himself, July 19.

Otto F. Fischer ⊕ St. Louis; Missouri Medical College, St. Louis, 1895; aged 60; died, July 13, in a hospital at Oshkosh, Wis., of a ruptured esophageal varix.

Wilbur Aaron Griffith, Coldwater, Mich.; Keokuk (Iowa) Medical College, 1898; served during the World War; aged 64; died, June 27, of chronic myocarditis.

Le Roy Pence, Lima, Ohio; Medical College of Ohio, Cincinnati, 1882; aged 76; died, July 10, in the Lima City Hospital, of cardiovascular renal disease.

John Hedges, Philadelphia; University of Pennsylvania School of Medicine, Philadelphia, 1901; aged 59; died, August 8, of chronic endocarditis and myocarditis.

Charles Ballance Holmes, Silver City, Miss.; Louisville (Ky.) Medical College, 1885; aged 68; was accidentally drowned, July 21, while fishing.

Alva Guy Thomas, Salt Lake City, Utah; Indiana University School of Medicine, 1917; aged 42; was found dead, July 21, of a gunshot wound.

Harriet Hodges Cobb, Cambridge, Mass.; Boston University School of Medicine, 1878; aged 93; died, July 11, in Medway, of arteriosclerosis.

George Westgate Mills, Medford, Mass.; Harvard University Medical School, Boston, 1879; aged 79; died, July 27, at Lexington, of heart disease.

Jack Hamilton Evans, Sault Ste. Marie, Ont., Canada; Queen's University Faculty of Medicine, Kingston, 1924; aged 35; was drowned, June 27.

Joshua Mearne Wardell ⊕ Cadillac, Mich.; University of Michigan Medical School, Ann Arbor, 1873; aged 77; died, August 1, of heart disease.

Deas Murphy, Litchfield, Conn.; Dartmouth Medical School, Hanover, N. H., 1897; aged 73; died, July 16, of carcinoma of the prostate.

Clyde Scott Roath, North Little Rock, Ark.; California Eclectic Medical College, Los Angeles, 1915; aged 55; was shot and killed, August 7.

John Johnson Fitzsimmons, Calcutta, Ohio; Starling Medical College, Columbus, 1895; aged 64; died, June 20, of poison, self administered.

Seaver Zerah Fisher, Brooklyn; Miami Medical College, Cincinnati, 1878; Civil War veteran; aged 87; died, July 9, of cerebral hemorrhage.

Buford R. Lancaster, Lakeland, Ky.; Cincinnati College of Medicine and Surgery, 1876; aged 79; died, July 20, of cerebral hemorrhage.

Edwin J. Turner, Columbus, Ga.; Flint Medical College of New Orleans University, 1902; aged 56; died, July 16, of acute myocarditis.

Henry Charles Wendel, Cincinnati; Miami Medical College, Cincinnati, 1894; aged 63; died, July 25, of acute dilatation of the heart.

James Henry Miller, Zanesville, Ohio; Leonard Medical School, Raleigh, N. C., 1911; aged 60; was drowned, July 27, while swimming.

George Wilson Lovan, Morton's Gap, Ky.; Kentucky School of Medicine, Louisville, 1892; aged 64; died, July 26, of heart disease.

George Washington Miller, Brockport, N. Y.; Detroit Medical College, 1871; aged 87; died, July 26, of senility and arteriosclerosis.

William Charles Davis ⊕ Chicago; College of Physicians and Surgeons, Keokuk, Iowa, 1878; aged 73; died, July 13, of myocarditis.

Harvey Lee Starkey, Wood River, Neb.; Barnes Medical College, St. Louis, 1899; aged 67; died, July 16, of chronic myocarditis.

George Edwin Bill, Harrisburg, Pa.; Harvard University Medical School, Boston, 1880; aged 78; died, July 28, of angina pectoris

S. D. Sluyter, Wolcott, Ind.; Kansas City Hospital College of Medicine, 1885; aged 75; died, July 24, of diabetes mellitus.

Perry F. Shaffer, Jacksonville, Fla.; Eclectic Medical Institute, Cincinnati, 1888; aged 65; died, July 20, of heart disease.

John Logan Brubaker ⊕ Deshler, Ohio; Toledo Medical College, 1898; aged 60; died, May 10.

Edward W. Boyd, Atlanta, Ga.; Atlanta Medical College, 1894; aged 56; died, July 13.

Bureau of Investigation

ADULTERATED OR MISBRANDED PHARMACEUTICALS

A List of Some of the Notices of Judgment Issued from July, 1931, to June, 1932, Inclusive, by the Food and Drug Administration, U. S. Department of Agriculture

[For many years, the Bureau of Investigation has published in this department, brief abstracts of Notices of Judgment issued by the Food and Drug Administration of the United States Department of Agriculture against "patent medicines." The number of proprietary preparations of this type that each year are found misbranded or adulterated is so large that these abstracts have to be published frequently.

The same officials that deal with cases of adulteration and misbranding in proprietary package medicines also, of course, act to protect the public against adulterated or misbranded official pharmaceuticals. As most official products are made by reputable pharmaceutical houses, the number of cases of adulteration or misbranding in this particular group is small compared with cases in the "patent medicine" group. For this reason, the Bureau of Investigation has made a practice of abstracting each year such Notices of Judgment as have been published by the government during the previous calendar year. In The Journal for June 25, this year, there was published a list of the Notices of Judgment issued during the first half of 1931, dealing with pharmaceuticals. We now present a list of similar notices issued from July, 1931, to June, 1932, inclusive. These are arranged alphabetically by products. First is given the name of the product, then follows the name of the manufacturer, shipper, or consigner; finally the number of the Notice of Judgment and the date of issue. It is to be borne in mind that the dates of publication of the Notices of Judgment are always several months later than the date of seizure of the product.]

Acetphenetidin Tablets.—Syracuse Pharmacal Company, Inc., Syracuse, N. Y. *(N. J. 18195; October, 1931.)*

Aconite Tincture.—Sharp and Dohme, Philadelphia. *(N. J. 18726; May, 1932.)*

Almond Oil.—Yglesias and Company, Inc., New York City. *(N. J. 18474, March, 1932; 18975, June, 1932.)* R. Fabien and Company, Inc., New York City. *(N. J. 18960; June, 1932.)*

Caffeine Citrated Tablets.—Syracuse Pharmacal Company, Inc., Syracuse, N. Y. *(N. J. 18195; October, 1931.)*

Chloroform.—No manufacturer's or shipper's name given. *(N. J. 18201; October, 1931.)*

Cinchophen Tablets.—C. E. Jamieson and Company, Detroit. *(N. J. 18308; January, 1932.)* Elmira Drug and Chemical Company, Elmira, N. Y. *(N. J. 18454; March, 1932.)*

Corrosive Sublimate Tablets.—Elmira Drug and Chemical Company, Elmira, N. Y. *(N. J. 18454; March, 1932.)*

Ergot.—Imported from Hamburg, Germany; name of importer not given. *(N. J. 18029; July, 1931.)* F. W. Berk and Company, Inc., New York City. *(N. J. 18189; October, 1931.)* J. L. Hopkins and Company, New York City. *(N. J. 18216; October, 1931.)*

Ergot, Fluid Extract.—John Wyeth and Bros., Inc., Philadelphia. *(N. J. 18304, January, 1932; 18466, 18520, March, 1932; 18957, June, 1932.)* Hance Bros. and White, Inc., Philadelphia. *(N. Correspondence

NEUROSES IN MAN AND ANIMALS

To the Editor:—Dr. Schilder, in writing on "The Somatic Basis of the Neurosis" (*J. Nerv. & Ment. Dis.* **70**:502 [Nov.] 1929), has discussed a portion of my work on conditioned reflexes in which I have produced what I have called neuroses. The author admits that "we can find all the phenomena of the neuroses." Such a statement from a competent source I, of course, greatly appreciate. But I must strenuously object to the statements of the author relating to the comparative studies of neuroses in man and in animals. The author says: "These important experiments of Pavlov and his school can be understood only if we look upon them in the light of our experiences in the neuroses. We cannot interpret the neurosis by means of the conditioned reflex, but by means of the psychic mechanisms we have studied in the neurosis we can certainly very well interpret what takes place in a conditioned reflex."

What is the meaning of the term "interpretation" or "understanding"? It is generally understood to mean an analysis of a more complex phenomenon in terms of more elemental and simple phenomena. Accordingly, the neuroses in man must be interpreted or understood, that is, analyzed, with the help of studies of neuroses in animals, which are naturally more simple, and not by the reverse procedure.

In man, it is first of all necessary to determine exactly wherein the deviation of behavior from the normal lies in the case concerned, for there is indeed a wide variation normally in the behavior of different people. And then one should search together with the patient, or apart from him, or even against his resistance, amid the chaos of affairs vital to him, for connections, conditions and situations that have acted at once or slowly, and with which perhaps the origin of the abnormal deviation may be justifiably linked—that is, for the origin of the neurosis. Moreover, it is necessary to understand why these conditions and situations have brought about such results in the patient, when in another person they would occur without the slightest effect; and, furthermore, why they all lead in the case of one person to just such an abnormal complex, while in another to a totally different one. I am taking only the principal group of points, omitting the vast range of those of more special nature.

But all this so far is only a part of the matter, if one undertakes a full and complete analysis of it. Of course, the change in behavior that is observed in a patient comes from a change in his nervous system. Who now will deny that? And so, an answer is still required to the question: How and why did the changes in the normal processes of his nervous system take place and of what sort were they, under the circumstances indicated?

Are not all these requirements real? And where are all these requirements satisfied?

With what does one deal in the dog? First of all, one sees that neuroses are possible to obtain and without difficulty, if only one has an animal in whose make-up there is not a proper balance between its fundamental reactions of nervous activity—as yet not further analyzed physiologically—that is, between the excitatory and inhibitory processes. This occurs either in an animal in which there is a marked predominance of excitatory processes over inhibitory, so that it is unable to exert *complete* inhibition over its actions when the situation demands it (excitatory type), or else in another in which, on the other hand, excitatory processes are so weak that the animal is often inhibited beyond proper limits, which is also inconsistent with the demands of life (inhibitory type).

Further, with such an experimental animal it is definitely known that this insufficient balance, peculiar to the make-up of the particular animal, finally breaks down under certain fundamental conditions. This happens mainly under three conditions, three circumstances. Either extremely strong stimuli in the nature of conditioned stimuli are used in the place of those that are only weak or moderately strong and which ordinarily determine the animal's activity; i. e., its excitatory processes are overstrained. Or the animal is required to exert a very strong or a very protracted inhibition; i. e., its inhibitory processes are overstrained. Or, finally, a conflict between both these processes is produced; i. e., conditioned positive and negative stimuli are applied one right after the other. In all these cases with the proper animal there develops a chronic disturbance of the higher nervous activity, *a neurosis*. The excitatory type loses almost completely its ability for any inhibition and generally becomes unusually excited; the inhibitory type, though hungry, refuses even to eat under the influence of the conditioned stimuli and generally becomes exceedingly ill at ease and also passive with the least change of its surrounding environment.

One can conceive in all likelihood that, if these dogs which have become ill could look back and tell what they had experienced on that occasion, they would not add a single thing to that which one would conjecture about their condition. All would declare that on every one of the occasions mentioned they were put through a difficult test, a hard situation. Some would report that they felt frequently unable to refrain from doing that which was forbidden and then they felt punished for doing it in one way or another, while others would say that they were totally, or just passively, unable to do what they usually had to do.

And so, what my associates and I have found with our animals is elemental physiologic phenomena—is the limit of physiologic analysis (in the present state of knowledge). At the same time it is the prime and most fundamental basis of human neurosis and serves as the truest interpretation and understanding of it.

Hence in the case of man, under the complications of his existence and with his many different reactions to it, when it comes to analysis and to the ultimate aim of curing him, one always has to face the very difficult question: "What circumstances in his life are excessively strong for the nervous system in question, where and when has he encountered a conflict intolerable for him, requirements that he become active and requirements that he hold himself back?

How in the opinion of Dr. Schilder could the innumerable subjective experiences of the neurotic patient under the extreme complexity of human higher nervous activity, as compared with dogs, give anything useful in the way of an explanation of the elementary neuroses of animals, when those experiences are only different variations of one and the same physiologic process, which is seen in dogs very distinctly?

Of course, for the final physiologic analysis of the problem of neuroses and psychoses there remain a number of undecided questions. Is it possible to produce neuroses in cases of well balanced nervous systems? Is the initial unbalance of the nervous system a primary phenomenon: i. e., an innate property of the nervous tissue itself, or a secondary one depending on some innate peculiarity of other systems of the organism apart from the nervous system? Do there not exist along with the innate properties of the nervous system also other conditions in the organism which determine this or that degree of normal function of that system?

I am busy at the present time with some of these questions and already have some material at hand for their decision.

It stands to reason that, apart from these special questions which concern the general problem of disorders of normal nervous activity, there remains before the physiologist the question relating to the physicochemical mechanism of these very elemental nervous processes: of excitation and inhibition, of their relationship, and of excessive strains on them.

I. P. Pavlov, Leningrad, Russia.

Queries and Minor Notes

Anonymous Communications and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

POISONOUS LACQUERS ON CHILDREN'S TOYS

To the Editor:—1. Is there a censorship of lacquers to cover and decorate children's toys? 2. Are lacquers containing such pigments as chrome yellow or chrome green regarded or disregarded as dangerous to the average child who occasionally puts a toy in his mouth? 3. Is there much lead poisoning from placing lacquered toys in the mouth?

Louis E. Bernheisel, M.D., West Collingswood, N. J.

Answer.—1. So far as is known, the elimination of lead coating for toys has been brought about by the agreements between manufacturers rather than by actual laws or regulations. In addition, the cost of lead is sufficiently higher than other useful coatings to favor the use of lead substitutes.

2. Inorganic chrome yellow is lead chromate; chrome orange is lead chromate plus varying proportions of lead oxide. Chrome green is chrome yellow mixed with prussian blue. These inorganic pigments are toxic. However, organic pigments frequently retain the name of earlier existing inorganic pigments. For example, organic chrome orange is a paranitrobenzene-azo-salicylic acid preparation. Organic pigments of this type are usually less toxic than the constituents used as intermediates. A preferance for stained toys is expressed rather than those so thickly coated that the paints may chip off and be ingested or lodge in the throat.

3. It is almost impossible to determine the extent of lead poisoning caused by the placing of toys in the mouth by children. This is due to the fact that small children, at least, are prone to place in their mouths flakes of paint picked off baseboards or dropped from walls or ceilings. Although cribs and childrens' furniture may not be coated with lead-bearing paints, full sized beds may be so finished. It is the general impression that lead poisoning of infants from toys is relatively infrequent and on the wane.

In every city, under present economic conditions, many toys are being reclaimed through such agencies as are attempting to increase employment. In addition, other unemployed individuals are engaged in making and peddling toys and novelties. Toys from these sources, rather than from standard manufacturers, are more likely to be the source of lead poisoning.

PURINES AND ACID PRODUCING FOODS

To the Editor.—Diet is attracting more attention in treatment, and the present tendency is to give a fairly high protein diet for Bright's disease, avoiding as far as possible purines, which I take as meaning practically the same as foods with an acid ash. I am puzzled over the question of eggs. In The Journal, March 3, 1923, page 647, eggs, butter, milk and cheese are classed as nonpurine. R. W. Wilcox (Treatment of Disease, 1919, p. 275) put these in the same category. On the other hand, William R. Warner & Company, Inc., in the "Calendar of Medical History," 1931, sixth page from the end, put eggs under acid producing foods, egg yolk being put as 26.69 per cent (exceeded only by oysters, 30 per cent). In the pamphlet issued by a proprietary house the same figures are used, and in The Journal, Jan. 11, 1930, page 141, eggs are classed under acid producing foods. Another company in its list does not seem to mention eggs under alkali producers. I would also like to know whether tomatoes tend to acidify or alkalize the urine. Please omit name.

M.D., Canada.

Answer.—The term "Bright's disease" should no longer be used unless the specific type of renal involvement is considered. The disease involving the parenchyma of the kidneys is an entirely different disease from nephrosis or from what is now termed nephrosclerosis. Nephrosis is a degenerative process of the tubules, and nephrosclerosis is a disease of the smaller arteries and arterioles of the kidneys. In the former disease a low protein diet has been used for years because it is in this disease that the blood shows a retention of nitrogen products. However, at a recent meeting of the American Association of Physicians, McCann of Rochester, N. Y., showed some case reports in which a higher protein diet was apparently not at all harmful. In nephrosis, a high protein-low fat diet is indicated. However, in nephrosclerosis, usually associated with hypertension and generalized cardiovascular disturbances, the therapeutic indications for diet are based on the cardiovascular complications rather than on the kidneys.

Purines are certainly not "practically the same as foods with an acid ash." A purine-free diet is indicated in gout, and because the purines are nucleoproteins they are not advised in glomerular nephritis. The best study of the relative acid-alkaline content of foods is the one by Sherman and Gettler. In their tables eggs are classified as acid-producing food on the basis of 11.1 per cent per hundred. Egg white is 5.24 per cent and egg yolk 24.69 per cent. On the other hand, eggs do not contain purine bodies. Practically all vegetables and fruits except cranberries, prunes, rhubarb and plums are alkali producing foods.

APHTHOUS STOMATITIS

To the Editor.—A single woman, aged 27, has aphthous stomatitis, which occurs more often at the menstrual period than at any other time. Otherwise she is well. Any cauterant aggravates, causing considerable inflammation in the surrounding tissue. Can you suggest any plan of treatment? Please omit name.

M.D., New York.

Answer.—The diet should be bland and should contain plenty of milk and spinach. The bowels should move regularly without excessive irritation from laxatives. Irritation of the mouth by strong tooth pastes, tooth powders or mouth washes should be avoided. Some calcium preparation should be given in adequate dosage for a week or more before the expected menstrual period. Of the lactate, given by mouth, from 3 to 5 Gm. should be taken after each meal, best with an equal amount of lactose dissolved in hot water.

DIGESTIBILITY OF EGGS

To the Editor.—Will you kindly inform me as to the comparative digestibility of hard and soft boiled eggs. Is the taking of raw eggs of any advantage? This question concerns a normal stomach. Is there any pathologic entity in which a hard boiled egg is preferable to a soft boiled or raw egg? Please omit name.

M.D., New York.

Answer.—Although there are many prejudices and opinions on the question of the way in which eggs should be cooked, the consensus seems to be that cooking does not radically interfere with the food value. Apparently the method of cooking does influence the speed of digestibility and perhaps to a lesser extent the appetite. Eventually, however, eggs in any form are well digested and absorbed no matter how cooked. An article entitled "Digestion in the Normal Human Stomach of Eggs Prepared in Different Ways," by R. J. Miller, H. L. Fowler, Olof Bergeim, M. E. Rehfuss and P. B. Hawk (*Am. J. Physiol.* **49**:254 [July] 1919) is the authority for the following statements: Soft boiling or poaching of eggs results in easier digestibility than either hard boiled or raw eggs. The raw white well beaten is also easily digested. The whole egg and hard boiled eggs are probably the most resistant to digestion. The only advantage in the taking of raw egg would be in connection with the egg albumin, which when given alone can be utilized in large amounts. There is an old practice among certain physicians of allowing ulcer patients to have a hard boiled egg at their bedside during sleep in case they are awakened by pain. A well masticated bite of the egg is supposed to relieve the pain.

SIMPSON MODIFICATION OF GILLIAM OPERATION FOR RETROVERSION

To the Editor.—Kindly inform me as to the steps of the Simpson modification of the Gilliam operation for retroverted uterus.

Eugene C. Lowe, M.D., Miami, Fla.

Answer.—After the peritoneal cavity has been opened, a ligature is passed about each round ligament about 1½ inches from the uterus, the ends of the ligatures being left long. Each is now separately threaded into a large pedicle needle and led through a small opening in the anterior surface of the broad ligament anterior to and just below the point where the ligature is located. By means of the pedicle needle, the ligature is carried between the leaves of the broad ligament and along the anterior abdominal wall just under the peritoneum until near the outer edge of the rectus abdominis muscle. Simpson then threaded the ligature on a full curved needle and carried it back into the peritoneal cavity, catching peritoneum, muscle and fascia, whereas Montgomery modified the procedure by carrying the ligature, and after it the round ligament, through the aponeurosis of the abdominal wall and fastened it there with chromic catgut.

WASSERMANN FAST SYPHILIS

To the Editor.—Recently I have had a patient under antisyphilitic treatment, a woman, aged 28, who had a chancre of the tongue when 6 years old. She has been treated since that time with arsenic, iodides and mercury and has always had a four plus Wassermann reaction. During this period of treatment she has had two rest periods of two years each. At the present time she has no superficial veins that can be used. Will you kindly advise me as to what form of treatment to use in this case and what I may expect from such treatment? Kindly omit name.

M.D., Oklahoma.

Answer.—It is apparent that this patient belongs to the so-called Wassermann fast type and that it would not be advisable to attempt to bring about a reversal of the positive Wassermann test by too intensive treatment. Intermittent medication with iodides by mouth and once or twice yearly a course of eight or ten injections of one of the standard bismuth or mercury preparations or sulpharsphenamine bismuth intramuscularly should be sufficient, provided there is no involvement of the central nervous system or of the cardiovascular mechanism. A serologic cure can hardly be expected in a long standing Wassermann positive case. A temporary reversal of the serologic reaction might be brought about by fever therapy.

DEATH FROM LIGHTNING, SUNSTROKE OR ANGINA PECTORIS

To the Editor.—A man, aged 41, apparently in good health, who had been shocking wheat, was found dead. His ears, neck and shoulders were mottled with apparent hemorrhages or stains of blood under the skin. The lips were blue. There was a cut on the back of the head, evidently from a fall. There was no evidence of fracture. The fingers were not clenched. There was no distortion in the face. The shirt was torn in back, his wife said that it was not torn before or at least when he put it on in the morning. The skin was mottled over the body in occasional spots similar to those on the ears, neck and shoulders. Was this man struck by lightning, as his people believe, or was it a coronary thrombosis? There were no evidences of a burn anywhere on his body. There were no trees in the vicinity. Please omit name.

M.D., Ohio.

Answer.—In some cases of death from lightning, no definite lesions have been found. In others there have been only small bluish or reddish spots and small hemorrhagic extravasations in the skin. There consequently is no reason at hand that could justify one in denying that death may have been caused by lightning. Appearances like those described are seen also in cases of death from sunstroke. It goes without saying that no opinion of any value may be ventured with respect to the suggestion that death may have been due to angina pectoris in the case in question.

MOLDY FOOD IN FOOD POISONING

To the Editor.—Are there any known evil effects of eating moldy food? E. L. Davis, M.D., Kijabe, Kenya Colony, East Africa.

Answer.—Moldy food has never been definitely implicated as a cause of food poisoning; that is, the products of the common molds (Penicillium, Mucor, Aspergillus) are not known to be toxic when swallowed. As is well known, certain species of Penicillium are habitually used for ripening Brie, Camembert and Roquefort cheese. Thom and Church (The Aspergilli, Baltimore, 1926, p. 89) cite experiments by Quevedo in South America made with a species of Aspergillus (A. maydis), which was thought by Quevedo to generate products toxic for horses and rabbits, but they add the comment: "The organism has not since been identified or studied in the light of more recent researches of forage poisoning. Until such repetition is possible, the results must now be regarded as questionable." The same authors also refer to more recent experiments in the Bureau of Chemistry, Washington, in which it was shown that grain inoculated with various species of Aspergillus and fed to horses and sheep over periods of from four to six weeks "failed to show evidence of toxicity itself or of infectivity due to the spores which filled the air which the animal breathed."

FACIAL TIC IN DOGS

To the Editor.—Our pet dog, on the day following contact with another dog that has had a unilateral facial tic for almost a year, developed a unilateral facial tic, which has persisted. Its onset was associated with a conjunctivitis of the eye of the same side of the face as the tic. Does there exist a contagious condition among dogs of this kind? If it is contagious, could human beings acquire it by close contact with such diseased dogs? Jacob A. Riese, M.D., West New York, N. J.

Answer.—Friedberger and Frohner, in their "Infective Diseases of Animals," make no mention of facial tic in dogs, nor does Moore in his "Pathology of Infectious Diseases of Animals." Medical literature does not contain any definite records of transfer from dog to man of any such condition as mentioned in the question.

USES OF YEAST

To the Editor.—Please advise me as to proper indications for the use of yeast, other than in the prevention and treatment of pellagra. What intestinal and skin diseases are benefited by its use? What contraindications exist? What are the differences in the effect of fresh yeast cakes and dried brewers' yeast? The popular mass advertising has caused much uncontrolled use of yeast. Please omit name and address.

M.D., Alabama.

Answer.—Aside from its value in vitamin deficiency and as a laxative, no other indications are definitely established. Its action in acne and furunculosis is so irregular as to be unpredictable. No contraindications have thus far been elaborated. There is no essential difference between the two forms of yeast mentioned.

SPECIFIC SENSITIVITY

To the Editor.—An unmarried school teacher, aged 40, comes to this locality each year and spends the summer. She complains that every summer, shortly after arriving, her face develops an intense itching and redness. She uses no soap or water on her face. The creams she uses were used before she came into the locality and caused no reaction. Her diet is not changed. She comes from Oregon, where redwoods and pines are common, to this locality where we have an abundance of oaks. In fact, a good part of the time she spends at a nearby farm where there are many oak trees. Physical examination, except for the diffuse maculopapular erythema of the face and a few papules on the outer aspects of both arms, is negative. Please suggest diagnosis and treatment. Please omit name.

M.D., Illinois.

Answer.—The problem here is not a simple one. It is apparent that the skin lesion is due either to external contact or to some food which the patient eats only in the summertime. The latter possibility can be readily ruled out by having the patient avoid such foods as corn, berries, cantaloup, watermelon and peaches. Contact dermatitis is more difficult to handle. The condition may be due to contact with some vegetation, as oak, primrose, grass or ragweed. Cases due to crysanthemum, tulip and others have been reported. It may also be due to contact with other substances, such as cosmetics, hair washes, lotions or furs. For contact dermatitis, the best method of determination is the contact or patch test, whereby the leaves or other substances to be tested are moistened and placed on a small square of gauze, applied to the back, covered with oiled silk, and held by two strips of adhesive plaster. If, when examined at the end of twenty-four, forty-eight or seventy-two hours, the areas show any redness, itching, or formation of vesicles, the reaction is considered positive. Many tests may be done at the same time.

To test for foods, the usual protein sensitization tests are indicated. They may give results or may fail. In any case they are to be checked by proper food elimination diets.

TREATMENT OF PULLED SHOULDER OR TRAUMA TO SHOULDER JOINT

To the Editor.—I have a patient, a girl, aged 12 years. Three or four years ago while in America she was crossing the street with her mother. An automobile had just passed and they did not see the oncoming car until right in front of it. To save her daughter the mother grabbed the girl by her left arm and threw her back out of the way of the car, which did, however, just strike her foot. The sudden strain on her arm so strained the ligaments that she feels her arm get out of place somewhat whenever she lifts or carries something a little heavy with that left arm. By pulling, the arm can be pulled out of its normal position for about an inch. What treatment would you suggest for the case? E. L. Davis, M.D., Kijabe, Kenya Colony, East Africa.

Answer.—The mother undoubtedly produced considerable trauma to the capsule of the shoulder joint, and possibly the circumflex nerve. This case corresponds with a subluxation almost like a mild, recurrent dislocation to the shoulder. It is sometimes spoken of as "pulled" shoulder. Some of these cases result in "snapping" shoulder.

In some of these cases the capsule of the shoulder joint is relaxed similarly to the condition seen in cases of poliomyelitis.

Recommendations include massage, contrast sprays, electrical stimulation, exercises, support for the shoulder to relieve gravity pull, and capsuloplasty, including imbrication of the capsule or quilting of the capsule.

In severe cases, suspension operations are indicated such as those described by Nicola and by Henderson.

FRACTURE OF CLAVICLE

To the Editor.—I have a patient who had a fracture of the right clavicle, the middle third. A T splint was applied for fourteen days, and then a figure-of-eight bandage. The union is good. However, a droop of the right shoulder developed. The callus is prominent. What is the prognosis? Will the callus be partly or totally absorbed? Kindly omit name.

M.D., Ohio.

Answer.—The callus will undoubtedly absorb sufficiently to preclude the necessity of operation. The droop of the shoulder is probably due to the traction on the brachial plexus caused by the weight of the arm. In most cases this can be avoided by wearing a sling for a few days in addition to the T splint.

BEDBUG INFESTATION

To the Editor.—Our Rod and Gun Club has a camp cabin infested with bedbugs. It is lined with tongue and grooved lumber but cannot be made air tight for fumigation. What is the best insecticide to use? When the clubhouse is closed this fall would it do any good to fumigate with cyanide gas? Any suggestions and plan for use would be greatly appreciated. Would you please answer at once? Please omit name.

M.D., Utah.

Answer.—Bedbug infestation in a camp cabin that is reasonably tight can be controlled, if not eradicated, by fumigation with hydrocyanic acid gas. Write the Bureau of Entomology, U. S. Department of Agriculture, Washington, D. C., for Farmers' Bulletin 1670, which contains information as to procedure.

"JELLYFISH AND STINGING NETTLES"

To the Editor.—In the April 9 issue of The Journal, a question was asked regarding treatment of the bites of jellyfish, or so-called Portuguese man-of-war. My experience in the South is that the Portuguese man-of-war is a balloon shaped blue fish, the balloon apparently filled with air, with long tentacles about the size of twine and varying from 1 to 2 or 3 feet long. These tentacles in the water come in contact with a person and adhere to the skin, even wrapping around the arm or leg. Apparently there is an oil on these tentacles which, when it strikes the skin, causes excruciating pain and the part affected can readily be mapped out with welts where the tentacles have become attached. The best treatment I have found for this is, considering it an oil, immediate washing with any cleaning fluid or gasoline to dissolve the oil, then thorough scrubbing with any harsh soap, and then application of any lotion, such as calamine, to allay irritation of the skin. This is painful until the oil is washed from the skin; then the local irritation subsides in about a day.

There is a peculiar rash which appears on bathers at different times during the month of February and March in Southern waters, which has been attributed to the spawn of jellyfish, but as yet I have never known a jellyfish of the ordinary sort to bite. This skin irritation is treated locally by application of some skin lotion.

Charles C. Morrison, Jr., M.D., Bar Harbor, Maine.

Council on Medical Education and Hospitals

COMING EXAMINATIONS

American Board of Obstetrics and Gynecology The examination *will be held in nineteen different cities in the United States and Canada,* Oct 22 Sec, Dr. Paul Titus, 1015 Highland Bldg, Pittsburgh

Arizona: Phoenix, Oct 3. Acting Sec, Dr. Jos M Greer, Professional Bldg, Phoenix

California. *Reciprocity* Los Angeles and San Francisco, Sept 21 *Regular* Sacramento, Oct 17 20 Sec, Dr. Charles B Pinkham, 420 State Office Bldg, Sacramento

Colorado Denver, Oct 4 Sec, Dr. William Whitridge Williams, 422 State Office Bldg, Denver

Connecticut *Basic Science* New Haven, Oct 8 Prerequisite to license examination Address, State Board of Healing Arts, 1895 Yale Station, New Haven.

Idaho. Boise, Oct 4. Dir, Bureau of License, Mr F L Cruikshank, Boise

Illinois: Chicago, Oct 18 20. Supt of Registration, Mr Paul B Johnson, Springfield

Michigan. Lansing, Oct 11-13 Sec, Dr Nelson McLaughlin, 1010 Maccabee Bldg, Detroit

Minnesota *Basic Science* Minneapolis, Oct 4-5 Sec, Dr J. Charnley McKinley, 126 Millard Hall, University of Minnesota, Minneapolis *Regular* Minneapolis, Oct 18 20 Sec, Dr E J Engberg, 524 Lowry Medical Arts Bldg, St Paul

Montana Helena, Oct. 4 Sec, Dr S A Cooney, Power Block, Helena

Nebraska: *Basic Science* Lincoln, Oct 4-5 Dir, Bureau of Examining Boards, Mrs Clark Perkins, State House, Lincoln

New Jersey Trenton, Oct 18 19. Sec, Dr James J. McGuire, 1101 Trenton Trust Bldg, Trenton

New Mexico. Santa Fe, Oct 10 11. Sec, Dr P G Cornish, Jr, 221 W. Central Ave, Albuquerque

Tennessee Memphis, Sept 29 30 Sec, Dr Alfred B DeLoach, Medical Arts Bldg, Memphis

Wyoming. Cheyenne, Oct 3. Sec, Dr W H Hassed, Capitol Bldg, Cheyenne.

Vermont June Report

Dr. W. Scott Nay, secretary, Vermont State Board of Medical Registration, reports the written examination held in Burlington, June 22-24, 1932. The examination covered 12 subjects and included 90 questions An average of 75 per cent was required to pass. Twenty candidates were examined, all of whom passed. The following colleges were represented

College — PASSED	Year Grad	Per Cent
Tufts College Medical School	(1932)	83 2
University of Vermont College of Medicine	(1930)	78, (1931) 79 4, 85 7, (1932) 83 6, 84 5, 85 3, 86 3, 86 3, 86 5, 87 3, 87 6, 87 8, 88 1, 88 4, 88 4, 88 7, 88 7, 90 1 *

Dr. Nay also reports 7 physicians licensed by endorsement from April 14 to July 20, 1932. The following colleges were represented:

College — LICENSED BY ENDORSEMENT	Year Grad	Endorsement of
State University of Iowa College of Medicine	(1929)	Iowa
University of Maryland School of Medicine	(1912)	Maryland
Tufts College Medical School	(1904)	New Hamp
Fordham University School of Medicine	(1917)	New York
Queen's University Faculty of Medicine	(1924)	Idaho
McGill University Faculty of Medicine	(1917)	Canada
Licentiate of the Royal College of Physicians and Surgeons, Edinburgh, and Royal Faculty of Physicians and Surgeons of Glasgow	(1931)	Scotland

* No grade reported License being withheld

Kentucky June Report

Dr. A. T. McCormack, secretary, Kentucky State Board of Health, reports the written examination held in Louisville, June 8-10, 1932 The examination covered 11 subjects and included 110 questions Sixty-four candidates were examined, all of whom passed. The following colleges were represented:

College — PASSED	Year Grad	Per Cent
University of Arkansas School of Medicine	(1932)	81
Loyola University School of Medicine	(1932)	85
University of Louisville School of Medicine	(1931)	88, (1932) 79, 80, 82, 82, 82, 83, 83, 83, 83, 83, 84, 84, 85, 85, 85, 85, 85, 85, 85, 85, 85, 85, 85, 86, 86, 86, 87, 87, 87, 87, 87, 87, 87, 87, 87, 87,* 88, 88, 88, 88, 88, 88, 88, 88, 89, 89, 89, 90, 91, 91, 91, 91, 92
Creighton University School of Medicine	(1932)	79, 83
University of Cincinnati College of Medicine	(1932)	87,† 88 †
University of Oklahoma School of Medicine	(1932)	85
Hahnemann Medical Coll and Hosp of Philadelphia	(1931)	82
University of Pennsylvania School of Medicine	(1931)	83
University of Tennessee College of Medicine	(1932)	85

Dr. McCormack also reports 5 physicians licensed by reciprocity with other states and 2 physicians licensed by endorsement from July 2 to Aug. 10, 1932. The following colleges were represented:

College — LICENSED BY RECIPROCITY	Year Grad	Reciprocity with
University of Arkansas School of Medicine	(1930)	Louisiana
Emory University School of Medicine	(1931)	W. Virginia
State University of Iowa College of Medicine	(1911)	Iowa
Creighton University School of Medicine	(1931)	Ohio
University of Cincinnati College of Medicine	(1932)	Ohio

College — LICENSED BY ENDORSEMENT	Year Grad	Endorsement of
University of Louisville School of Med	(1925), (1931)	N B. M. Ex.

* Diploma withheld

† These applicants have received an M B. degree and will receive an M D degree on completion of an internship.

District of Columbia July Report

Dr. W C. Fowler, secretary, Commission on Licensure, District of Columbia, reports the written examination held in Washington, July 11-12, 1932. Twenty-eight candidates were examined, 27 of whom passed and one failed. The following colleges were represented:

College — PASSED	Year Grad.	Number Passed
College of Medical Evangelists	(1932)	1
Georgetown University School of Medicine	(1931, 5)	5
George Washington University School of Medicine	(1931, 12)	12
Howard University College of Medicine	(1931, 2)	2
Northwestern University Medical School	(1906), (1931)	2
Rush Medical [illegible]	(1922)	1
University of [illegible]	[illegible]932)	1
University of [illegible]	[illegible]930)	1
Royal Hungar[illegible] Budapest	[illegible],* [illegible]925)	2

College — FAILED	Year Grad.	Number Failed
Georgetown University School of Medicine	(1930)	1

Dr Fowler also reports 11 physicians licensed by reciprocity *with other states from Jan. 14 to July 18, 1932. The following colleges were represented:*

College — LICENSED BY RECIPROCITY	Year Grad	Reciprocity with
Georgetown University School of Medicine	(1908)	Connecticut
George Washington University School of Medicine	(1928)	New York,
	(1930)	Maryland
Howard University School of Medicine	(1929)	N Carolina
Johns Hopkins University School of Medicine	(1902)	Maryland
University of Maryland School of Medicine and College of Physicians and Surgeons	(1929), (1930)	Maryland
University of Buffalo School of Medicine	(1923)	New York
Medical College of Virginia	(1929)	Virginia
University of Virginia Department of Med	(1907), (1924)	Virginia

* Verification of graduation in process.

Alabama July Report

Dr J N Baker, secretary, Alabama State Board of Medical Examiners, reports the written examination held in Montgomery, July 11, 1932. The examination covered 10 subjects and included 100 questions An average of 75 per cent was required to pass. Ten candidates were examined, all of whom passed The following colleges were represented:

College — PASSED	Year Grad	Per Cent
University of Arkansas School of Medicine	(1931)	83 7
Rush Medical College	(1932)	85 5,* 87 3*
University of Louisville School of Medicine	(1931)	85 8
Tulane University of Louisiana School of Medicine	(1932)	85 1, 86 5, 86 8, 88 2
University of Tennessee College of Medicine	(1932)	84 4
Vanderbilt University School of Medicine	(1932)	88 6

Dr. Baker also reports 7 physicians licensed by reciprocity with other states and one physician licensed by endorsement from Jan 21 to July 12, 1932. The following colleges were represented.

College — LICENSED BY RECIPROCITY	Year Grad	Reciprocity with
Emory University School of Medicine	(1931)	Georgia
Rush Medical College	(1930)	Illinois
University of Minnesota Medical School	(1929)	Minnesota
Meharry Medical College	(1928)	Tennessee
Baylor University College of Medicine	(1930)	Louisiana
University of Virginia Department of Medicine	(1928)	Virginia
University of Naples Faculty of Med and Surgery	(1923)	Illinois

College — LICENSED BY ENDORSEMENT	Year Grad	Endorsement of
Harvard University Medical School	(1929)	N B M Ex

* These applicants have received their four year certificate and will receive their M D degree on completion of an internship

Book Notices

Epidemiologische en bacteriologische gegevens over het roodvonk. Door Dr. J. Goudsmit. Bekroond antwoord op de prijsvraag uitgeschreven door de Nederlandsche Maatschappij tot Bevordering der Geneeskunst. Cloth. Pp. 311, with illustrations. Amsterdam: F. Van Rossen, 1932.

This work is the prize winning answer to the following thesis propounded by the Dutch Society for the Advancement of Medicine at Amsterdam: "Data, partly based on personal observations, are requested concerning the epidemiology of scarlet fever, taking into consideration the question of contagion by inanimate objects and making use of the modern reactions of immunity." The author devotes the first part of his work to a review of the literature on the etiology and pathogenesis of scarlet fever, with especial reference to Streptococcus hemolyticus, Dick's toxin and the meaning of Dick's immunity reaction. In the second part he deals with transmission of the disease through the various known agencies and from the point of view of the streptococcus theory. In the third part he discusses from the endemic point of view (1) the influence of the factors of age, race, sex, season, and the like, on the incidence of scarlet fever, taking for granted that Dick's reaction furnishes an index of the susceptibility to the disease; (2) the relations between virus, individual and group, with especial reference to the streptococcus as the causative agent, and (3) the application of the previously obtained data. In the fourth part he treats of scarlet fever epidemics, describes their changeable course and attempts to explain it from the point of view of our actual knowledge of surrounding conditions. The fifth part deals shortly with prophylactic and therapeutic measures. The author concludes his work with the statement that his investigations do not allow him to declare himself decisively for or against the streptococcus theory of scarlet fever. The book is carefully planned, well subdivided and connected and gives the reader a clear understanding of the subject under consideration.

Habits for Safety: A Text-Book for Schools. By Harry W. Gentles, of First Aid Life Saving, Chicago Chapter American Red Cross, and George H. Betts, Director of Educational Research, Northwestern University. Cloth. Price, 67 cents. Pp. 228, with illustrations. Indianapolis: Bobbs-Merrill Company, 1932.

These authors are particularly well equipped to prepare this type of book. Dr. Gentles is chairman of first aid life saving for the Chicago chapter of the American Red Cross and Mr. Betts is director of educational research in Northwestern University. It is becoming generally recognized that death by accident accounts for 100,000 lives annually. There are, moreover, some 10,000,000 injuries with a loss of billions of dollars due to absence from work and payment of compensation. The handbook called "Habits for Safety" is planned particularly for the young, since it is in youth that habits of safety must be developed. Various chapters in this book deal with safety in the home, at school, on the street, on the farm and in play. There are also chapters on the prevention of fires and electrical accidents, on the safety of the worker and on the administration of first aid.

Beiträge zur Physiologie des Hirnstammes. Von Prof. Dr. W. R. Hess, Direktor des Physiologischen Institutes der Universität Zürich. Teil 1: Die Methodik der lokalisierten Reizung und Ausschaltung subkortikaler Hirnabschnitte. Von Prof. Dr. W. R. Hess. Paper. Price, 24 marks. Pp. 122, with 114 illustrations. Leipzig: Georg Thieme, 1932.

This volume represents the first part of a series of contributions to the physiology of the brain stem and contains the description of the experimental method of the author. A cat is anesthetized by nitrous oxide and placed on the operating table; electrodes are then mounted on its head by means of special electrode holders, which are screwed on the skull. Electrodes with two or more poles have been used, each pole carrying two needles; they are inserted into the brain stem through small burr holes, and the brain is stimulated electrically after the animal has recovered from the anesthetic. Half an hour after the experiment, which is always photographed by a cinecamera, the cat is killed and the brain fixed by solution of formaldehyde. After twenty-four hours the electrodes are removed and the part of the brain containing the stimulated points is used for histologic purposes. Every area affected by the points of the electrodes is indicated by figures on enlarged photomicrographs, which are taken from serial sections. The whole set of these sections represents the "atlas of stimulated points." Every effect that has been observed during the experiments is registered in the so-called directory of symptoms, together with a description of the way it has been obtained. The information gathered by the stimulation experiments is completed by a series of experiments during which a coagulating current is introduced into the brain stem, so as to destroy certain points. The volume contains an extraordinarily detailed and elaborate description of every step of the experimental procedure, and of the various pieces of apparatus. A knowledge of the method used by the author is of great value for any one who is occupied in experimental neurology.

A Short Introduction to the History of Human Stupidity. By Walter B. Pitkin. Cloth. Price, $3.50. Pp. 574. New York: Simon & Schuster, 1932.

After Sinclair Lewis wrote "Babbitt," he pointed out that even the best of us are Babbitts and that even the smartest man may have Babbitt characteristics. Professor Pitkin has made a survey of stupidity among the great, among nations and races, indeed, such a massive array of stupidity in general as to convince the reader that stupidity is everywhere and that one is warranted in indicting Professor Pitkin for stupidity for making so much of stupidity. One need not search far to understand why human beings are stupid. It is simply because they are human beings.

Division palatine, anatomie, chirurgie, phonétique. Par Victor Veau, chirurgien de l'Hôpital des Enfants Assistés. Avec la collaboration de Mlle. S. Borel. Paper. Price, 140 francs. Pp. 568, with 786 illustrations. Paris: Masson & Cie, 1931.

This book presents the experience of the author in doing 500 cleft palate operations. From the introduction one feels that he has made the best of his experience and has set down his voluminous observations in a frank manner that stimulates the reader in the study and, more than that, wins him to the spirit of the author.

The book is divided into three parts: Anatomy constitutes the first part. Four types of cleft are distinguished: (1) simple cleft of the soft palate, 20.8 per cent; (2) simple cleft of the soft and hard palate without harelip and with the alveolus intact, 30.8 per cent; (3) unilateral cleft palate with the alveolus cleft, 38.8 per cent; (4) bilateral cleft palate with complete isolation of the median tubercle, 9.6 per cent. Surgical anatomy of all component structures is discussed at length and with many illustrations, and, following these studies, the author has outlined operations for as close as possible anatomic restorations.

The second part deals with the surgery of cleft palate. The methods of others are discussed at some length, and several pages are occupied with Lexer's ideas on the subject, which are generally adverse to those of the author. There is apparently a complete list of methods proposed for closing the palate where classic methods fail, and there is a list of "monstruosités chirurgicales" which includes operations to close the defect with flaps brought in from elsewhere in the body. The bad results of operation and reasons for them by the classic methods are discussed from anatomic and functional standpoints. There now follow case reports of the 500 operations. These range in length from half a line to several pages, and there are numerous illustrations, mostly line drawings of operations. In this section almost any type of cleft is to be found with a description of the author's closure. Statistics from all angles are listed. The total mortality has been 3.8 per cent (19 deaths out of 500), and it is interesting to note the decreasing mortality with the increase in years: one year, 9.4 per cent; two years, 5.7 per cent, three years, 2.7 per cent; four years, 1.8 per cent. Under the heading of statistics comes the discussion concerning the age at which the operation should be done. The author's ideas might be said to be reduced to mathematical accuracy. One who is in a quandary over this point must surely find solace in this small section. 1. The mortality is an argument in favor of late operation. 2. The speech is an argument in favor of early operation. It is shown that, in children operated on in the first year, speech is 70 per cent normal; in the second year, 69 per cent; but in the third year, 26 per cent. The optimal age for closing a cleft palate is between the twelfth and the twenty-fourth month; the mortality is 5.7 per cent, and the speech function is 69.6 per cent. However, these total statistics may be presented to the parents and the decision made by them. Veau agrees with Berry that the occasional operator had best wait for the later age. The statistics on anatomic closure show 15 unclosed palates, 26 holes behind the alveolus and 24 holes at the junction of the hard and soft palate.

The third part is said by the author to be the main aim of the book and deals with his technic for the closure of the four forms originally distinguished. In the first type, simple cleft of the velum, closure is effected by sutures along the nasal and buccal surface and a wire around the muscle bundle. No lateral incisions are made. The steps are made clear by twenty-eight illustrations. In the second type, cleft palate without cleft lip or alveolus, closure similar to the first type is done, but lateral flaps are raised over the hard palate and switched toward the median line. In the third type, complete cleft with harelip, a flap is taken from the vomer and turned over on itself to make a nasal lining, a palate flap from the cleft side is raised and carried over to the under surface of the vomer flap and held there apparently with one suture, and the vomer flap is then closed entirely through the alveolus with a flap turned similarly from the nasal, alveolar and buccal fornix mucosa. The soft palate is closed at another operation. For the fourth type, bilateral cleft palate and lip, essentially the same process is carried out as that in the third type, except that there are flaps taken from both sides of the vomer. Only one illustration accompanies this type of closure, and the author states that he writes this chapter with timidity because he has not had sufficient experience to state with authority the value of the method he proposes. The final chapters, on speech, include studies by Mlle. Borel on the physiology of speech in patients with cleft palate, and on the training of speech after operation.

The book stands as a monumental work to the author. There is such volume to it that it may be taken as a standard reference on the subject. The bibliography is excellent and, furthermore, is referred to generally in the text. Cleft palate will be found to be a complicated surgical problem; thorough study of the book might discourage some from attempting the work, but no one who does the work should omit a thorough study of it.

Man and Medicine: An Introduction to Medical Knowledge. By Dr. Henry E. Sigerist, Professor at the University of Leipzig. Introduction by Dr. William H. Welch, Professor of the History of Medicine, the Johns Hopkins University. Translated by Margaret Galt Boise. Cloth. Price, $4. Pp. 340. New York: W. W. Norton & Company, Inc., 1932.

Professor Sigerist has just taken the chair of the history of medicine in Johns Hopkins University. The book here presented has had a remarkable success in Germany, where there would appear to be a far greater number of intelligent laymen interested in medical knowledge than in this country. The book is divided roughly into parts dealing with man, disease, medical aid and the physician. It presents not only an outline history of medicine, written in exceptionally good English, but also a philosophy of medicine and a vast amount of fundamental medical knowledge. It is hard to believe that any person could be considered well educated without the information that Professor Sigerist here makes available. The layman who wishes a better understanding of current trends in medicine will find in this book the orientation that he desires.

Produktive Diabetikerfürsorge. Von Prof. Dr. Alfred Lublin und Dr. Robert Kroner, Assistenten der Medizin. Universitatsklinik und Poliklinik, Greifswald. Ein Bericht über Ziele und Erfahrungen des ersten deutschen Diabetikerheimes in Garz auf Rügen. Mit einem Geleitwort von Prof. Dr. Gerhardt Katsch, Direktor der Medizin. Universitätsklinik und Poliklinik, Greifswald. Paper. Price, 6 marks. Pp. 92. Leipzig: Georg Thieme, 1932.

This booklet gives the results of a year's experience with more than 200 patients in a newly erected German institution. This first German diabetic home was built for the purpose of aiding diabetic patients during the present economic conditions in Germany with a minimum of expense and an optimum of results. Much stress was laid on the fact that diabetic patients are unable to find work in the days of unemployment of millions of healthy people and therefore suffer from an inferiority complex in view of their own physical illness. Every effort was made to find some kind of occupation for every patient. The type of work depended on the stage of the disease and on the patient's previous education and experience. Thus a happy mental equilibrium was created which was thought to be of great importance for a successful diabetic treatment. The patients worked in the offices, laboratories, kitchens, the garden and the farm of the institution. In fact, all the employees of the home have diabetes. Their work was satisfactory throughout.

The main purpose of the medical treatment was to find the optimum in the carbohydrate tolerance, not while the patient was inactive but while in the routine of moderate physical exercise and work. The average duration of treatment of patients with mild and moderately severe diabetes was 32 days and in severe instances 132 days. No death was reported. The authors' experiences regarding the physical activities of their patients are summarized in their statement that neither the carbohydrate metabolic disturbance nor the general condition in a single patient showed any turn for the worse. However, an improvement of the carbohydrate tolerance that could be interpreted as being due to muscular activity was not observed. This is in contradistinction to the researches of Buerger and others, who reported favorable results in patients who were treated with insulin and who were kept at voluntary muscular activity. The authors emphasize the favorable effects of a diet poor in fat and rich in protein and carbohydrate as recommended by Porges and Adlersberg in cases of severe carbohydrate disturbances. The booklet is comprehensive and contains many valuable and concise statements. It may be recommended to any one interested in the modern treatment of diabetic patients.

Protective Measures Against Dangers Resulting From the Use of Radium, Roentgen and Ultra-Violet Rays. By Professor Hermann Wintz, M.D., Ph.D., Director of the University Gynæcological Clinic and Roentgen Institute, Erlangen. With the Assistance of Privatdozent Walther Rump, Ph.D. League of Nations, Health Organisation. Series of League of Nations Publications, III. Health. 1931. III. 9. Official No.: C. H. 1054. Paper. Price, 75 cents; 3/-. Pp. 114. Boston: World Peace Foundation; Geneva: League of Nations, 1931.

The chapters in this book concern prevention against dangers caused by radiation and against electrical accidents. They also cover hygienic measures in radiation establishments, and measures against the dangers of x-ray fires. Obviously the prevention of harm from the x-rays is concerned largely with dosage and with the use of suitable screens. A complete bibliography is offered as a supplement to the volume.

In considering the disasters that have resulted and the dangers that have developed due to storage of x-ray films, Professor Wintz points out that compliance with some of the regulations is practically impossible. He feels that the regulations issued by the German ministry of the interior, providing that fireproof safes be used for storage, so far as small stores of up to 15,000 films are concerned, are quite sufficient. He feels also that more importance should be attached to proper handling of x-ray films, for a small quantity of film, incautiously handled, is just as capable of causing a dangerous fire as a larger quantity.

Plastic Surgery of the Nose, Ear and Face. By Dr. Victor Frühwald. Translated by Geoffrey Morey, M.B., B.S., D.L.O., Junior Surgeon Shropshire Nose, Ear and Eye Hospital (Shrewsbury). Cloth. Price, $4. Pp. 86, with 88 illustrations. Vienna: Wilhelm Maudrich, 1932.

This is a short book written mainly for doctors who have worked with the author. It includes cosmetic surgery of the nose and ear and technic for the removal of wrinkles and folds from the face. The rasp is used to remove bony nasal humps, and ivory implants are recommended for saddle nose. The author has listed the deformities that he believes are the most commonly encountered, such as small hump nose, large hump nose, wide nose, saddle nose, alar deformities, large ears, prominent ears, and wrinkles of the face. For each of these there is a description of the author's technic of operation, and credit is given other surgeons when their methods are used. The author has not published any "before and after" photographs because he believes they are of no particular use to the reader.

Report of the Permanent Commission on Biological Standardisation (London, June 23rd, 1931). League of Nations, Health Organisation. Series of League of Nations Publications, III. Health, 1931. III. 10. Official No.: C. H. 1056 (I). Paper. Price, 40 cents; 1/6. Pp. 78. Boston: World Peace Foundation; Geneva: League of Nations, 1931.

This pamphlet is concerned with the standards adapted in various parts of the world for antitoxin, tuberculins, serums, biologic products for veterinary use, sex hormones and vitamins. It makes available the vitamin standards developed at the meeting in London in June, 1931.

Medicolegal

Malpractice Suit No Bar to Subsequent Action on Contract to Cure

(McQuaid v. Michou (N. H.), 157 Atl. 881)

The plaintiff brought an action for damages against the defendant-physician, charging him with negligence in treating her. There was a judgment in favor of the physician. Thereafter, the plaintiff brought another action against the physician, charging him with a breach of an express contract to cure. From a verdict for the plaintiff, the physician brought exceptions to the Supreme Court of New Hampshire.

The present suit is not barred, said the Supreme Court, because the existence of a promise to cure may have been an issue in the prior suit. If it was an issue, it was only a collateral one, not essential as an element of the cause of action. The prior suit was for improper treatment. This action is for failure of a promised result of treatment. The physician's liability in this action depends, continued the court, not on the character of his conduct but on his agreement for its results. How he acted is now only of collateral bearing, while in the prior suit it was only of collateral bearing what he agreed to do. The verdict in the prior suit shows that the physician's treatment of the plaintiff was proper and skilful, but it does not show what his undertaking was as to the outcome of the treatment. The fact that in the prior suit the plaintiff based her claim on improper treatment does not bar her present claim of proper treatment barren of promised results. While the plaintiff in this action may not find fault with the treatment she received, she may say that it did not do for her what the physician promised. If the physician had promised to pay the plaintiff a stipulated amount if he did not cure her, the defense that he had used due care and skill would be of no avail. The contract here falls short of such a promise only in its deficiency of provision for liquidated damages.

Apparently, the plaintiff did not complete the full course of treatments the physician wished to give. This conduct on the part of the patient, the physician claimed, was a breach of the contract on her part. The evidence, said the court, authorized a conclusion that the plaintiff did not complete the treatment because it affected her health too seriously. The physician contended that the verdict in the prior suit determined this issue of her fault against her. The verdict in the prior suit, said the court, exonerated the physician from blame for the treatment, but it did not show that the plaintiff was at fault for the results of the treatment. Responsibility for the results was not necessarily hers merely because it was not the physician's. A contract to cure is against public policy, the physician further contended, in that its enforcement would tend to dissuade a physician from encouraging his patients by giving them hope as an important aid to their improvement or recovery. The line between a promise and an opinion, said the court, is not so narrow and shadowy that language may not be well chosen to express one in clear distinction from the other. It is a simple matter for a physician to make it definite that he guarantees no good results. If a promise to cure were held illegal, a patient ignorant of its illegality would be misled in placing reliance on it. If he were aware of its lack of binding force, his knowledge would tend to prevent confidence in it, and the gain to be expected from freedom of statement would be lost in its known irresponsibility.

The trial court declined to charge the jury, at the physician's request, that the plaintiff could not recover unless she believed that the defendant would cure her, or if both parties knew her disease to be incurable. Expectation on the plaintiff's part, said the court, that the promise to cure would be fulfilled, was not necessary to give it contractual effect. When a thing is promised, it is of no consequence whether or not the promisee expects performance. If both parties knew the disease was incurable, however, then they knew that the promise could not be performed. Contracts known by the contracting parties to be impossible of performance are void and the jury should have been so instructed. If, however, the terms of the contract limited the duration and severity of the treatment, the plaintiff may recover damages for any conditions or results of the treatment in excess of the limits, although both parties knew the disease was incurable. If the plaintiff knew she could not be cured, she took the treatment with some thought that it might help her. If it hurt her beyond what it was agreed it would, and if she incurred expense and loss of earnings on that account, she may claim a breach of the terms of the agreement in regard thereto, even if the knowledge of both parties that she could not be cured made the promise to cure ineffective.

The rule of damages, said the court, in a suit alleging breach of contract to cure, gives as compensation only the difference between the condition promised and the actual condition, including incidental consequences fairly subject to contemplation by the parties when the contract is made. The actual condition may include suffering as an attendant feature of it, and hence such suffering may be shown. Suffering, however, incident to treatment may not be taken into consideration in the computation of damages. For error of the trial court in instructing the jury concerning the measure of damages, the Supreme Court overruled the verdict for the plaintiff and remanded the case for a new trial.

Unlawful Practice of Medicine by Chiropractor.—Robertus, a chiropractor, treated a patient, after examination, "for misalignment of certain joints of the vertebrae and spine." He used no drugs nor surgical instruments. He was convicted of practicing medicine without a license and appealed to the court of criminal appeals of Texas. The medical practice act of Texas, said the appellate court, has often been held constitutional. In *Hicks* v. *State*, 88 Texas Cr. R. 438, 227 S. W. 302, the court said:

> The law as a law appears to be made equally for all who fairly come within its comprehension, and, as far as we know, prescribes no examination conforming to the technical requirements of any school or branch of medical practice, and is not violative of the tenets of article 16, section 31, of our constitution, which commands laws prescribing the qualifications of physicians, and forbids preference by law to any school of medicine.

The trial court did not err in permitting a witness to testify, over objection, concerning the number of her visits to Robertus' office for treatment. Neither did the court err in refusing to permit a patient of Robertus to state what her condition was after she had been treated by him. Such evidence, said the court, could in no way mitigate against the question of guilt. The trial court refused to permit Robertus to answer a question as to whether or not he practiced medicine. Whether or not Robertus did practice medicine was a conclusion of fact for the jury to decide, said the appellate court. The question asked called for an opinion on the part of Robertus, and the answer thereto would not only amount to a mere opinion or conclusion but would be an opinion or conclusion which the witness could not be permitted to testify to because it involved the whole merits of the controversy. The mere fact that a prospective juror may have been treated by a chiropractor does not disqualify him as a juror in the trial of a chiropractor for violating the medical practice act. The conviction was affirmed. —*Robertus v. State (Texas), 45 S. W. (2d) 595.*

Workmen's Compensation Acts: Refusal to Undergo Operation.—An employee, in the course of his employment, injured his arm and sought compensation under the workmen's compensation act of Oklahoma. Physicians testified at the hearing that the disability might be removed by a major surgical operation, but the employee refused to submit to the operation. The industrial commission awarded compensation and the employer and his insurance carrier appealed to the Supreme Court of Oklahoma. Whether or not, said the court, an employee may be barred from compensation because he refuses to submit to an operation depends on the nature of the operation. If it is a major operation, involving the slightest risk to life, the employee has the right to refuse to submit to it. He may choose whether he desires to suffer from the disability for the rest of his life or whether he shall take the risk of a surgical operation in order to lessen the disability. In any event, said the court, the employee is entitled to compensation.—*King Drilling Co. v. Massenburg (Okla.), 7 P. (2d) 454.*

Oregon State Medical Society, Klamath Falls Sept 22 24 Dr Albert W Holman, 410 Taylor Street, Portland, Secretary

Pennsylvania, Medical Society of the State of Pittsburgh October 3 6 Dr Walter F Donaldson, 500 Penn Avenue, Pittsburgh Secretary

Vermont State Medical Society Burlington October 6 7 Dr William G Ricker, 31 Main Street, St Johnsbury, Secretary

Virginia Medical Society of, Richmond November 1 3 Miss Agnes V Edwards, 1200 East Clay Street, Richmond, Secretary

CONFERENCE ON RHEUMATIC DISEASES

Held Under Sponsorship of the American Committee for the Control of Rheumatism New Orleans, May 9, 1932

Work of the American Committee for the Control of Rheumatism

Dr Ralph Pemberton, Philadelphia Arthritis is the oldest disease on record and is the cause of more pensionable invalidism than any other condition except cardiovascular disease of old age The medical profession has more or less ignored it, and because of this indifference there has long existed an attitude of pessimism concerning it About eight years ago in Europe was created the "Ligue Internationale Contre le Rheumatisme" Five years ago the American Committee for the Control of Rheumatism was formed to act in affiliation with the Ligue, to provide for the standardization of treatment of sufferers from arthritis, to stimulate investigation, and to endeavor to extend sound information regarding it to the medical and lay public alike

The committee recognizes two great types of chronic arthritis, the atrophic or rheumatoid, and hypertrophic or osteo-arthritic It has published a "Concept," and "Outline" and a "Primer" dealing with the general nature of the rheumatoid problem and setting forth certain basal etiologic, pathologic and therapeutic considerations about which there can be no serious or radical differences of opinion Scientific exhibits on arthritis were presented at the annual sessions of the American Medical Association in 1930, 1931 and 1932 Clinics have been established in various parts of the country, where treatment has brought help to many sufferers from arthritis

In order to arrange some formal expression of the views and experiences of others, the committee called this meeting

Clinical and Economic Features of Arthritis in 450 Ex-Members of the Military Service

Dr Philip B Matz, Washington, D C During 1931, about 35,000 ex-service men received over $10,000,000 in disability compensation caused by arthritis, a number constituting 6 4 per cent of all beneficiaries of the Veterans' Administration, and a sum constituting 4 7 per cent of all veterans' benefits Five degrees of impairment of earning capacity are recognized officially temporary partial, temporary total, permanent partial, permanent total and double permanent total disability A group of 450 cases in the hospital for special study included 213 cases of hypertrophic arthritis, 172 of atrophic arthritis, 31 of hypertrophic spondylitis, 14 of "specific" infectious arthritis (gonorrheal, tuberculous), ten of rheumatic fever, and ten miscellaneous In only 17 per cent of the cases was there evidence of hereditary or familial history of disease of the joints Exposure and trauma were the chief predisposing factors A study of dietary habits did not indicate that overindulgence in food is a predisposing factor No relationship of endocrine disturbance or allergy to the inception of arthritis was found Focal infection was prominent although not the sole antecedent factor Patients with hypertrophic spondylitis had an average of five and seven-tenths acute exacerbations, and those with specific arthritis an average of two For the entire group there was an average of four exacerbations for each patient, and the mean duration of disease of the joints was 130 months Improvement was noted in 76 per cent of the cases

DISCUSSION

Dr P S Hench, Rochester, Minn Does the question of malingering present a serious problem? It is often difficult to prove the presence of organic disease in patients complaining of diffuse pains in muscles and about joints when no objective articular phenomena, muscle spasms or atrophy, are present The results of roentgen examination and other laboratory tests do not help much In the Veterans' Bureau, arthritis is a compensatory disability If there is a question of money return, especially in times of economic stress, human nature has not changed and the soldier may feel disabled from aches and pains little beyond the "normal"

Dr J L Dubrow, Memphis, Tenn Electrocardiographic studies similar to those recently reported by Master and Jaffe and the sedimentation test are of diagnostic and prognostic value

Dr P B Matz, Washington, D C I cannot state how many patients gave a history and subjective symptoms of arthritis and were found on examination not to have any disability No doubt a number of such patients are drawing compensation, but they cannot escape detection long, as examinations for rating purposes are very carefully done and include roentgenographic and objective evidence

Dr Ralph Pemberton, Philadelphia Many of Dr Matz's patients, at the onset of atrophic arthritis, were overweight, a condition somewhat contrary to general experience Obviously, some were ingesting more food than they could adequately care for, a recognized factor in the rheumatoid syndrome

The Relationship of Endocrine Disturbance to Arthritis

Dr Francis C Hall, Boston Thyroid deficiency appears to be one of the contributing etiologic factors Among 150 patients with hypertrophic arthritis, symptoms and signs of hypothyroidism occurred with great frequency Basal metabolic rates were below —10 in 50 per cent, and below —15 in 34 per cent of 108 patients The patients were in general well nourished, and no other explanation for hypometabolism was apparent except glandular deficiency Treatment with thyroid gland was of permanent benefit to 49 per cent of 116 patients to whom it was administered Among 150 patients with atrophic arthritis, stigmas of hypothyroidism were encountered less frequently and if present might have been accounted for by depletion and undernutrition Metabolic rates were below —10 in 35 6 per cent and below —15 in 17 7 per cent of 103 patients Treatment with thyroid gland was of permanent value to only 16 5 per cent of 103 patients, it probably helps by providing better nutrition to joints

Relation of the Digestive Tract to Arthritis

Dr T Preston White, Charlotte, N C The role of focal infection and its removal is not as important as the discovery and correction of metabolic errors Ninety-nine cases of atrophic and 112 of hypertrophic arthritis were studied Only three of thirty patients with atrophic arthritis and only one of thirty-four patients with hypertrophic arthritis received benefit, and that only temporary, from dental extractions. Only 17 per cent of about fifty patients with atrophic arthritis and 13 per cent of about sixty with hypertrophic arthritis experienced relief from tonsillectomy. Focal removal seems to help only about 10 to 15 per cent of all patients with arthritis and may make 5 per cent of them worse. Of both types observed, 85 per cent of the patients ingested starches excessively, 80 per cent were habitually constipated, and about 40 to 50 per cent were obese. The treatment included Pemberton's (low calory, low carbohydrate) diet, laxatives, increased periods of rest, and physical therapy. Removal of foci, and vaccines played a minor part. About 75 per cent of patients were improved.

DISCUSSION

Dr. R. Garfield Snyder, New York: Dietary control is essential, but low colonic irrigations with plain or medicated water are an important therapeutic addition. In spite of criticism of this form of treatment, experience with more than 16,000 irrigations in the treatment of more than 1,000 patients with arthritis seems to show that recovery is hastened and that no injury to the colon results.

Dr., A. R. Shands, Durham, N. C.: I cannot agree that untoward results do not follow colonic injections. They seem to cause dizziness and extreme weakness in older patients, necessitating their discontinuance. Others are markedly benefited; one patient, bedridden for two or three years, was able to walk after three irrigations. As a rule, those who are going to be improved thereby begin to show some relief after the second or third irrigation. To obtain maximum results from vaccine, colonic irrigations or other treatment, careful attention must be paid to the factor of diet, a matter so far unsettled, as there is no complete understanding of what aberrations in digestive function occur in cases of chronic arthritis.

Dr. Earl D. McBride, Oklahoma City: The laborers in the oil fields of Oklahoma eat heartily and chiefly of meat, beans, potatoes and bread. They are subject to traumatic disorders, chiefly backstrain. An intestinal tract thus overloaded plays an important part in prolonging disability. Trauma and then toxins from food lower the resistance of joints to focal infection, which is ever present and which soon gains headway.

Dr. Robert B. Osgood, Boston: Although several factors, climate, diet, rest and infection, are important in chronic disease, a consideration of the gastro-intestinal tract in chronic arthritis is perhaps most important. Physicians should never fail to study the demands of combustion and elimination. In a large percentage of cases there is evidence in the stools of indigestion caused by starch and of fermentation. An excess of carbohydrate seems to be the chief offender.

Dr. Paul A. McIlhenny, New Orleans: Ten constipated patients were treated by simple carthartics alone, and ten others with cathartics and high colonic irrigations. Improvement was more decided in the latter group than in the former.

Dr. T. Preston White, Charlotte, N. C.: In my experience colonic irrigations have been unnecessary when proper diet, laxatives, postural exercises and rest are employed. The expense of long continued irrigations must be considered.

Coexistent Chronic Infectious (Atrophic) Arthritis and Cholecystitis: Results of Cholecystectomy

Drs. E. Starr Judd and Philip S. Hench, Rochester, Minn.: Although the gallbladder is not a common focus, it is infected in about 3 to 5 per cent of cases of chronic infectious (atrophic) arthritis. In some cases cholecystitis and infections of joints bear an indirect relationship, both probably arising from some other and primary focus. In other cases, infections of the gallbladder may serve as a focus for arthritis, as it may harbor organisms, generally streptococci, occasionally staphylococci or bacilli, capable of producing experimental lesions in the joints and gallbladders of animals. Bacteriologic and pathologic observations have been made in fifty-five cases of chronic infectious arthritis in which cholecystectomy for coexistent gallbladder disease was performed. In several cases, gallbladder tissue contained arthrotropic organisms. In five of the cases, symptoms related to the joints were completely relieved. In eleven cases there was marked improvement, and in eight definite, although moderate, relief followed operation, a total of 52 per cent. The joints of the remaining twenty-one patients were not appreciably affected by cholecystectomy. These observers concluded that when definite surgical indications for cholecystectomy are present it is justifiable to urge surgical intervention in the biliary tract in the hope that the arthritis may be definitely benefited. Further experience is necessary before one can urge removal of the gallbladder for arthritis when the indications for operation, aside from the arthritis, are not definite. A conservative attitude is probably desirable, yet the nature of chronic infectious arthritis is so malicious that a radical attitude in individual instances may be justified, provided surgery is advocated and accepted without unwarranted promise of benefit.

DISCUSSION

Dr. R. Garfield Snyder, New York: Stones or disease of the gallbladder have been found in only 12 of 981 cases of chronic arthritis. Cholecystectomy was performed in two cases, and in addition to relief of the biliary disturbance, both patients reported a rather marked improvement in the symptoms of arthritis, an improvement that has persisted. Hartung and Steinbrocker found infection of the gallbladder in only 4.5 per cent of 200 patients with chronic rheumatism, an incidence no higher than in any other group of general cases in the hospital. Medical treatment has seemed preferable to surgical in my cases: diet, colonic irrigations and nonsurgical drainage of the gallbladder by the Lyon method, the benefits of which seem to be due not so much to drainage of the gallbladder as to drainage of the liver itself, have been employed.

The Climatic Factor in the Treatment of Rheumatic Disease

Dr. W. Paul Holbrook, Tucson, Ariz.: Climate is not a panacea for all rheumatic diseases, and other treatment should not be neglected. The argument in favor of climatic treatment is based on the low incidence of rheumatic disease among local Indians, Mexicans and white persons resident in and near Tucson as compared with the incidence elsewhere, and the results of such treatment in a group of 500 patients with rheumatic fever and chronic arthritis. In cases of recurrent rheumatic fever, referred to Arizona for treatment, all evidence of activity subsided during the patients' stay, and in a large proportion of those with chronic arthritis, even of an advanced state, gratifying results were obtained by general care and climatic treatment alone. The total effect of climate is a composite of humidity, temperature range, barometric pressure, wind velocity, rainfall, concentration of ultraviolet rays, total sun energy, ionization of the air, type and character of exposure to sun, and the like. Studies are being carried on to determine which are the significant factors and how they work.

The Desensitization Treatment of Chronic Arthritis

Dr. James C. Small, Philadelphia: The rationale of the desensitization treatment rests on the hypothesis that patients with arthritis have acquired hypersensitive states. The hypersensitive properties of their tissues are acquired from multiple contacts with some foreign substance. In the case of arthritis this substance is provided by the establishment of a focus of infection and of auto-inoculation thereafter. The treatment consists of subcutaneous injections of minute doses of a saline extract of Streptococcus cardioarthritidis. Vaccines from this organism are too toxic for use. The dosages of the saline extract which give beneficial results seem so small as to appear beyond the limits of reason, but as further experience with dosage has been acquired, more and more patients with arthritis have responded favorably. Moderate overdosage leads to prompt and sharp, unfavorable reactions; an apparent paradox appears in that marked overdosage is followed not by prompt but by delayed reaction, appearing only after two or three days and which may, unless recognized and subsequent doses corrected, lead to progressive disability. No stated schedule of antigen dosage can be prearranged, as the injections may activate foci of infection and cause further auto-inoculation. The opsonic index is used to gage the dose. The benefits are not derived from the foreign protein content of the antigen but may depend on the presence of bacterial polysaccharides devoid of sensitizing properties but yet effective in reducing an existing hypersensitization.

Intravenous Vaccine Therapy in Chronic Arthritis

Drs. Macnider Wetherby and B. J. Clawson, Minneapolis: Vaccines from one strain of streptococcus, isolated from a patient with rheumatic fever, are used in the treatment of rheumatic fever, atrophic (rheumatoid) and hypertrophic (osteo) arthritis alike since we believe that no distinct separation of these diseases is warranted. This view is based on the isolation of streptococci from the blood, the common presence of subcutaneous nodules, the similar reactions of streptococcal skin tests, common biologic relationship of the streptococci isolated in all three conditions, and the favorable clinical response of all types to the intravenous streptococcic vaccine therapy, this one strain alone being used. It is of low virulence, it is not a self agglutinator, and it cross agglutinates in high titer with many other strains of streptococci from patients with rheumatic fever and chronic arthritis. The vaccine is given intravenously because Clawson's experimental work on animals showed that streptococci injected subcutaneously may render animals hypersensitive and produce only a moderate degree of protection, while intravenous injection produced desensitization and, more important, a high degree of protection by antibody formation. An initial dose of 100,000,000 bacteria is given and weekly subsequent injections are increased from 100,000,000 up to 800,000,000 organisms. Fever and chills are frequently experienced. Of 300 patients with chronic arthritis so treated, 80 per cent were clinically improved. The degree of improvement bore no relation to the degree of reaction following the injection. Improvement was manifest in most cases after five injections. The agglutinating titer of the patient's blood rises during treatment and improvement is not, as a rule, noted until the titer has risen to 1 : 6,400, or more. The height of the agglutinating titer in most cases seems to be a reliable indication of the degree of protective immunity to streptococci provided to the patient.

DISCUSSION ON PAPERS OF DR. HOLBROOK, DR. SMALL, AND DRS. WETHERBY AND CLAWSON

Dr. John W. Gray, Newark, N. J.: The great army of sufferers from the North cannot be imported to tropical climates and means must be sought of combating the disease where it occurs. With Dr. Gowan, by a modification of Cecil's method, I have isolated streptococci from the blood in 61 per cent of 144 patients with rheumatoid arthritis. Cultures in 133 control cases were essentially sterile. Positive cultures were obtained in from one to three days without opening the containers. Vaccine subcutaneously was abandoned in favor of intravenous injections, the strains isolated being used. An initial dose of 100,000 only was used, and if with increasing amounts discomfort and increased pain in the joints were experienced, the dose was greatly reduced or the vaccine was discontinued temporarily.

Dr. William J. Kerr, San Francisco: Perhaps the common denominator in all these methods of treatment, vaccines, peptone, amidoxylbenzoate, physical therapy of various sorts, sympathectomy and diets, is the improvement of the local circulation to joints. Whether the beneficial results of vaccines are brought about by release of antibodies or by a change in the physical state of the blood is not known. Vaccines can increase the surface temperature of the body. Some foci of infection develop not before but after the appearance of arthritis, probably because of the general condition of the patient. Streptococci are ubiquitous organisms and perhaps the experience that was had with Hodgkin's disease a few years ago is being reported. If enough blood is taken enough times from a patient with a chronic disease and if delicate methods of culture are used best suited for the growth of the organism that is being looked for, perhaps the same thing could be found in many chronic diseases. Most important in treatment is the improvement of the general condition of the patient by all means at hand.

Dr. O. O. Ashworth, Richmond, Va.: Using a modification of Cecil's method, I have isolated streptococci from the blood of 56 of 138 patients with rheumatoid arthritis. In thirteen cases a gram-positive diplococcus was recovered and by Mellon's culture method these diphtheroids assumed a true streptococcal form. Blood cultures from more than 100 cases of hypertrophic arthritis were negative. Small doses of autogenous vaccines were given intravenously and marked improvement was obtained in 53 per cent of 122 cases of rheumatoid arthritis so treated, improvement generally beginning after a few injections.

Dr. Russell L. Cecil, New York: Probably no two of the hundred physicians present have the same ideas about the disease. Get three or four together who are interested in arthritis, and one can start a fight almost any time. As to cutaneous reactions to streptococci, some give a marked reaction, others none at all. When foci of infection are removed early and promptly, nature will often heal the infected joints. Then removal of foci often marks the turning point in the patient's condition. Late in the disease, focal infection plays a minor part; and after three or four years of the disease, it does not make much difference whether or not the foci are removed. There are so many kinds of vaccines, it leaves one in doubt as to where to start. Dr. Small uses small doses, Dr. Wetherby large. The differences in terminology given to the various streptococci used for vaccines should not be a cause for confusion. One may speak of hemolytic streptococci, another of green streptococci, yet be describing the same organism, as the differences in appearance are often due to the culture mediums used. In view of the high agglutinins in patient's serum, the experimental arthritis produced and the high percentage of recovery, I cannot feel that the germs isolated by myself and my colleagues were contaminants.

Dr. Reginald Burbank, New York: Dr. Small and other advocates of small dosages of bacterial products are attempting desensitization rather than immunization. Small doses tend to decrease formation of antibodies against infective streptococci, whereas massive doses increase such formation and agglutination titer. Both methods can give favorable results. Small dosage is more satisfactory in the long run even though results are slower. Adverse climate is not, per se, conducive to arthritis. Among the Eskimos the disease is almost unknown, as it is in Denmark and Iceland. In other sunnier and warmer climes it is common.

Dr. A. Almon Fletcher, Toronto: I doubt that Wetherby's method of using large doses of vaccine over short periods of time will have permanent value. A rise in blood agglutinins does not always indicate favorable change. I have seen patients improve while the level of blood agglutinins was falling. Faulty diets, inadequate in vitamins and unbalanced in food factors, predispose to the development of the disease, but it may take years for the influence of suboptimal diets to become apparent. An extended trial of dietetic measures is indicated.

Dr. John H. Musser, New Orleans: Since I have been in New Orleans I have seen practically no cases of arthritis, in contrast to my experience in Philadelphia, where 50 per cent of patients in wards of hospitals had arthritis.

Dr. R. E. Utley, Harlingen, Texas: I have never seen acute rheumatism and rarely find a patient with chronic arthritis resident in the extreme southwest of Texas, where there is a low altitude and a dry, semitropical climate.

Dr. Ralph Pemberton, Philadelphia: Various factors have each an influence and are not at all incompatible one with the other. The successful treatment of arthritis today depends on seeing the problem whole rather than from any single angle of vision, and on advancing a therapeutic program which considers in a coordinated way its various aspects.

Dr. James C. Small, Philadelphia: I question the value of using the patient's agglutinin titer as an index of his immunity. In order to maintain a high titer there must be available from time to time a certain amount of antigen. Patients with an active focus maintain a high agglutinin titer, which gradually becomes less when foci are eliminated.

Dr. Macnider Wetherby, Minneapolis: My experience with intravenous typhoid vaccine has been unsatisfactory in most cases, and raising the agglutinins for typhoid bacilli to a titer of 1 : 200,000 had no effect on increasing streptococcal agglutinins, whereas the patient with more active involvement tends to have a high agglutination titer, which falls as the activity subsides; this is not comparable to the artificial elevation of agglutinin titer by intravenous vaccine. In such cases there is generally correlation among the agglutinin titer, the clinical improvement and, more significant, the bactericidal power of the blood for streptococci.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to The Journal in continental United States and Canada for a period of three days. Issues of periodicals are kept on file for a period of five years only. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending, but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Passage of Urea Between Blood and Lumen of Small Intestine. W. R. Pendleton and F. E. West, Los Angeles.—p. 391.

Note on Relationship of Cerebrospinal and Intralabyrinthine Pressures. W. Hughson, Baltimore.—p. 396.

Effect of Lumbar Sympathectomy on Flow of Blood in Femoral Artery.—Herrick and his associates made a series of studies on the flow in the femoral artery of the dog. A comparison was made of the minute volume flow in the right and left femoral arteries, both local and general anesthesia being used. After unilateral sympathectomy the flow was again measured. The results show that the flow is the same in the two femoral arteries of the normal dog. Following unilateral sympathectomy, the flow in the femoral artery on the sympathectomized side is about twice as great as that on the intact side. When ether anesthesia is used in place of local infiltration, the difference between the intact and the sympathectomized side is not conspicuous. The authors conclude that surgical ether anesthesia is almost as effective as sympathectomy in producing vasodilatation.

Histamine as Hormone for Gastric Secretion.—Sacks and his associates isolated histamine from acid extracts of the pyloric mucosa as a sulphate and picrate. The method is described. Vasodepressor and secretory assays on all fractions from the original acid extract to the final product of histamine crystals and mother liquor yield strong, if not conclusive, evidence that histamine is the sole secretory excitant active subcutaneously in acid extracts of the pyloric mucosa and that histamine was not produced by the chemical procedures employed. Histamine (0.5 to 1 mg.), pilocarpine (5 to 10 mg.) and isopilocarpine (10 mg.) are the only imidazoles out of ten tried that stimulate gastric secretion. Methylene histamine (5 to 10 mg.) does not stimulate gastric secretion. A threshold dose of a gastric secretory excitant is present in 1 or more liters of urine, which is to be expected on the basis of the histamine content of urine. Histaminase destroys the gastric secretory effectiveness of "gastrin" solutions. Histamine adsorbed to Lloyd's reagent maintains its vasodepressor and secretory properties.

Albuminuria Following Exercise.—From forty-seven individuals, Hellebrandt made analyses of the urine collected immediately following experimental bouts of physical exertion of various types, such as riding the bicycle ergometer, running around an indoor track at top speed, and working in a rowing machine. It was noted that the incidence of albuminuria increased from 14.8 per cent before exercise to 57.5 per cent after exercise. The pulse pressure fell below normal in all cases after a half hour bicycle ergometer ride. The pulse pressure fall in the cases with postexercise albuminuria was 90.1 per cent greater in depth and was maintained 41.8 per cent longer than the pulse pressure fall in the cases without albumin following physical exertion. The greatest amount of albumin was found to occur during the period of oliguria and the maximal reduction in the amplitude of the pulse pressure. The author explains the experimental results by the hypothesis that strenuous exercise shunts the blood to the working muscles and the skin, affecting the circulation of the kidney in such a way as to cause asphyxiation of the renal cells beyond that compatible with normal function. The deep and protracted postexercise low pulse pressure adds to the anoxemia already present and induces an abnormal accumulation of acids in the renal tissue which alters its permeability to the blood proteins and albumin appears in the urine.

Tuberculosis of Vertebral Body.—Doub and Badgley call attention to the fact that the roentgenologist must know the pathologic changes in tuberculosis of the spine and must be able to correlate these with the corresponding roentgen signs. A series of 100 cases are included in their study. The age incidence in the series was studied; the average was found to be 29 years. The average duration of symptoms at the first examination was six and one-half years. The mode of infection is discussed and the hematogenous route is favored, but the lymphogenous route may also play a part. A suggestion is made that in some cases the primary infection may be in the disk. Roentgenologically, the authors distinguish the following types of tuberculous involvement of the body of the vertebra: (1) central type; (2) intervertebral articular type, and (3) anterior type. They tabulate the frequency of the various types of infection according to the location in the spine and find that the central type of lesion is more common in the thoracic area and that the intervertebral type is more common in the lumbar area. The central type causes collapse of the body of the vertebra in a high percentage of cases, while in the intervertebral type the vertebral body form is preserved until late in the disease. Narrowing of the disk is the earliest and most constant roentgen sign in tuberculosis of the spine. Abscess is the most common complication and was found in 84 per cent of the authors' cases at some stage of the disease. Skipped infection, or two areas of infection with normal vertebrae between, was found in 10 per cent of the cases. Concomitant tuberculosis in other parts of the body was found in fifty-three instances. The pulmonary lesion was the most common concomitant lesion and was present in twenty-four cases.

Colon as Studied by Double Contrast Enema.—Gershon-Cohen and Shay state that the double contrast enema aids in the roentgen diagnosis of spasms and adhesions of the colon, it makes possible elimination of errors in diagnosis due to filling defects, the result of incomplete filling and spasm It allows a more conclusive differentiation from the roentgen observations alone between irritable colon and so-called spastic colitis and true inflammatory and ulcerative colitis It is a distinct advance in the roentgen diagnosis of ileocecal tuberculosis, simplifying greatly the procedure of study recommended thus far by the best investigators in this field who have been using the opaque medium by mouth Additional roentgen signs are made available in the diagnosis of chronic ulcerative colitis Additional information is furnished by the double contrast roentgenograms in determining the actual number and extent of diverticula of the colon and the presence or absence of concomitant inflammatory changes in any of them Early neoplastic growths, long before they produce filling defects in the single contrast enema films, are detectable in the double contrast roentgenograms and open the way for the surgeon to go a step further, by their early removal, in the prevention of malignant degeneration The authors recommend the double contrast enema study as an additional routine examination to the ordinary enema study of the colon because it always furnishes a check duplicate study of the colon, it lends confirmatory aid and makes possible the detection of valuable supplementary observations in cases ordinarily studied with difficulty by the single contrast enema, and, lastly, it makes possible the detection of lesions not suspected or demonstrable by the single contrast method alone

Evaluation of High Voltage Roentgen Rays in Therapy of Carcinoma of Cervix.—Behney points out that high voltage roentgen therapy is a distinct addition to the present therapeutic armamentarium for the treatment of carcinoma of the cervix. Used in addition to local radon applications in stage 3 and earlier cases, it will increase the expectancy of life Local irradiation of the growth should be practiced in all cases earlier than stage 4 The therapy of patients whose lesions have advanced to stage 4 should be confined to external short wavelength radiations in the form of high voltage roentgen rays or packs. In late cases this treatment prolongs life, reduces pain, and restores hope Recurrent cases must be individualized and the plan of treatment should depend on the degree of extension of the growth and the general condition of each particular patient.

Tuberculosis Among Medical Students J Steidl, Boston —p 98

Nodules of Experimental Tuberculosis.—Sewall and his associates give an account of the development of the primary nodule of tuberculosis in the guinea-pig, with its vascular supply and associated tissue changes. They noted that the incubation period of the primary nodule varies somewhat inversely with the infecting dose and seems shortened by tissue irritation. Apparently, forces of stimulation and inhibition are coordinated in the development of the nodule. Infections with 0 01 mg. of a pure culture of tubercle bacilli may cause slight subcutaneous tissue condensations in advance of nodule formation. Such deposits greatly increased up to the authors' maximum dose of 10 mg. They are of inflammatory origin and are probably due to nonspecific chemical irritation resulting in fixation of the water of edema. With large bacillary doses, from 1 to 10 mg, the acceleration and physical characters of the effects of infection closely resemble those commonly described as peculiar to reinfection. When a guinea-pig is infected in one groin and then on successive days is reinfected in the other, a nodule is formed after the secondary dose similar in physical character and history to the primary nodule. But the incubation period of the second nodule is apparently progressively slightly shortened from the first day, as compared with that of primary infection in the experimental and control animals. When the interval between infection and reinfection reaches about seven days, the latent period of the nodule of reinfection is suddenly greatly decreased, this is about the time required for development of the primary nodule of infection on the opposite side. Thereafter the response to reinfection maintains its acceleration, whatever the interval

Fluttering of Abdominal Viscera.—Ehrenburg reports that roentgen examination in cases in which left-sided phrenic avulsion was performed revealed displacement of the stomach and duodenum to the left and upward. This displacement is considerably greater in inspiration than in expiration. The shape of the duodenum (normally, at roentgen examination, the bulb and pars descendens form a sharp angle) undergoes a considerable change and presents an arch approaching a straight line By comparing the inspiratory and expiratory roentgenograms, one can recognize a swinging of the pylorus and duodenum from right to left and back again, the excursion being about two inches The stomach shows a large bubble of air, which is belched up easily and is replaced in a few seconds. High tonus of the stomach and duodenum is present. The stomach empties rapidly, usually in two hours. The swinging of the duodenum causes a constant irritation of this viscus, which is apparently chiefly responsible for the various manifestations of indigestion These digestive disturbances do not interfere with recovery, though in some cases they are annoying. Light meals at frequent intervals alleviate the symptoms. The author regards "fluttering of the abdominal viscera" as the proper name for this complication.

Vaccine Therapy in Chronic Arthritis.—In 301 cases of chronic arthritis, Clawson and Wetherby gave five or more intravenous injections of a streptococcus vaccine at weekly intervals. The organism used in the vaccine was from a case of acute rheumatic fever and had been growing in culture for nine years, was of low virulence, did not agglutinate spontaneously, and was safe for intravenous injections Cross agglutination occurred in high dilutions (1: 50,000) with many other strains of both acute rheumatic and chronic arthritis origins The initial dose was 100 million organisms This was increased by 100 million organisms at weekly injections. As a rule, not more than eight or ten injections were given. Slight reactions with temperature and chills occurred in about 50 per cent of the cases The degree of reaction seemed to have no relation to the clinical improvement. Nearly two thirds of the patients experiencing improvement did so after five injections; nine tenths did so after seven injections. There were only a few cases in which improvement took place if it had not occurred with eight or ten injections. Definite clinical improvement was observed in 80 per cent of the cases.

Hypertension and Diabetes.—John states that the blood pressure in nondiabetic persons rises proportionately higher in the case of obese individuals than in those of normal weight (approximately 12 per cent increase). Reduction in weight in nondiabetic persons brings about reduction in blood pressure. In the author's series of 1,828 cases of diabetes, the blood pressure was the same as in normal persons below and including the fourth decade; above this age the incidence of high blood pressure was greater in diabetic persons. In his series of 443 cases of diabetes associated with hyperthyroidism, 37.6 per cent of the patients had a blood pressure below 140 mm. and 62.4 per cent had a blood pressure above 140 mm., against 54.3 and 45.7 per cent, respectively, in diabetes not associated with hyperthyroidism. In his series of cases the diabetic persons up to 30 years of age showed hypertension only in 9 per cent, whereas in diabetic persons with hyperthyroidism, hypertension was present in 42 per cent of this group of young individuals. Up to the fifth decade, hypertension in itself presents no marked incidence of diabetes; after the fifth decade the incidence rises markedly.

Fallacy of Weighed Diet in Treatment of Diabetes Mellitus.—When Ulrich began to treat diabetes he followed the prevalent custom of prescribing weighed diets, but he soon abandoned that method. During the past ten years he has not asked one of his patients to follow it. He is using more easily understood household measures and natural food units in his dietetic prescriptions and presents a table showing a day's ration by which approximate accuracy is reached without the use of the scales. The percentages of carbohydrate, protein and fat in this table are rough approximations only, but he is confident that they are nearly as accurate as if the food had been weighed with the utmost care. This statement is supported by the results obtained with a group of patients who received an unweighed diet and whose level of the blood sugar was determined on several consecutive mornings before breakfast. A comparison of these results with others obtained with patients receiving a weighed diet showed no significant differences in regard to the daily variations of the blood sugar. The author is aware that dietetic prescriptions by weights and calories are easier for the physician. He uses them constantly in the hospital where the services of a trained dietitian are available. Outside the hospital, however, the burden of translating such a prescription into a day's menu is placed on the patient. A few patients have sufficient leisure, inclination and intelligence to do it in a satisfactory manner; many more have not. They should not be required to perform a task that properly belongs to the physician.

Hypothyroidism Without Myxedema. — Youmans and Riven believe that hypothyroidism without myxedema is a more common condition than is generally appreciated and is not confined to regions where goiter is frequent. Failure to recognize the disease is due to the vague symptomatology and to the fact that the signs and symptoms of myxedema, the better known hypothyroid state, are lacking. The diagnosis depends largely on the detection of an abnormally low basal metabolic rate; but this observation must be interpreted with caution, since low rates are not all due to hypothyroidism. In diagnosis, the nature of the response to thyroid substance, which is specific in true hypothyroidism, is of great importance and serves to distinguish between lowered metabolic rates due to hypothyroidism and those due to other causes.

Fractures of Neck of Femur.—Gill states that, in fractures of the neck of the femur, some patients on admission to the hospital are not fit subjects for any treatment directed toward the reduction and fixation of the fracture. There is a high mortality, probably 25 per cent, when all cases of fracture are included in the statistical tables. The mortality rate increases rapidly beyond the age of 60. Nonoperative methods of treatment of recent fractures will continue to be used in the majority of cases. Of these the Whitman abduction method has given the best results. Open operation should be the method of choice in selected cases. The most common causes of nonunion are failure in making a diagnosis of fracture, and improper treatment in cases that have been correctly diagnosed. But nonunion may be expected in 20 to 25 per cent of the cases treated by the Whitman method or by open operation. The rate is low in patients under 60 years and increases rapidly beyond this age. In ununited fracture, if the head is viable and if a fair portion of the neck has survived, union may be hoped for in 75 to 90 per cent by means of an autogenous bone graft or a Smith-Petersen nail. Satisfactory union should not be expected in the presence of necrosis of the head, and rapid and complete absorption of the neck. For this group of cases a reconstruction operation offers a 75 per cent chance of securing good function in patients under 60 years of age. In patients beyond this age, its advantages are doubtful. Arthrodesis of the hip affords relief to some patients after any or all of the operations mentioned have failed. If it becomes possible to select early in their history those cases that are doomed to failure of union by any method of treatment, an early arthrodesis will avoid months and years of useless treatment and disability.

Fat Embolism.—Wright presents the clinical and pathologic aspects of fat embolism. He reports two cases of this condition, one resulting in death and the other in recovery. A digest of 100 consecutive necropsies as regards this condition is presented. The author believes that fat embolism should be considered in any case in which there are grave or unusual symptoms following trauma, whether the trauma is fracture, contusion, concussion, intravenous therapy, delivery or operation.

Intravenous Injection of Pituitary Extracts.—Geiling and DeLawder present experimental data from which the following conclusions seem warranted: After the injection of solution of pituitary and pitressin there follows for a short period (the stage of maximum action) a state resembling anaerobic metabolism in the tissues drained by the superficial and deep leg veins of dogs. During this time the venous blood is characterized by an arterial-like color and oxygen content, a lowered carbon dioxide tension, a rapidly rising lactic acid concentration, increased dextrose and inorganic phosphate. This is the period of decreased cardiac output and lowered basal metabolism. Following this stage of tissue asphyxia is the recovery period, when conditions are reversed: an abnormally dark venous blood, increased utilization of oxygen and production of carbon dioxide by the tissues, and a continued rise and subsequent gradual return of blood lactic acid to the preinjection level. Blood drawn from the external jugular vein (having a mixed drainage area, brain, muscle, and so on) in the period of the so-called maximum action of solution of pituitary and pitressin indicates a different effect of these drugs in this region. In contrast to the arterial-like leg sample, the jugular blood is more venous in color and has a decreased oxygen content, only a slight, if any alteration in the carbon dioxide concentration, and a lactic acid increase similar to that in the femoral *blood. The return of the basal level roughly parallels the* recovery period indicated in the blood draining the limbs.

Experimental Streptococcic Arthritis.—By injecting certain mannite-fermenting arthrotropic streptococci, isolated from the blood stream of afebrile arthritic patients, Hadjopoulos and Burbank were able to produce in rabbits pathologic lesions exactly comparable to those found in chronic arthritis in the human being. By incubating the whole joint they were able to demonstrate these infecting organisms in practically all lesions associated with chronic atrophic arthropathies. Streptococci were found in every part of the synovial tissues where pathologic changes could be detected. No streptococci could be demonstrated in compact bone, yet the spread of infection in bone tissue could be traced step by step through its medullary and haversian vascular supply. In the avascular cartilage, the spread of streptococci was through infected bone tissue and synovial infiltration. Normal joints were subjected to the same procedure with uniformly negative results. To complete the picture of infection, the authors have recently studied the tendons and muscles in the immediate neighborhood of arthritic joints. They had no difficulty in demonstrating streptococci in tendons at the zone of nuclear proliferation. Muscles were extensively infiltrated with streptococci at their sheaths, but in spite of great care the possibility of outside contamination in surface areas must be considered. Throughout this study the progress of the disease could always be traced directly to the terminal blood vessels, as is true in all infections of hematogenous origin. Despite the specific selectivity of the arthrotropic streptococci used in these experiments, internal organs, especially the liver and kidneys, were not exempt from pathologic changes of toxic nature involving their parenchyma. Nevertheless, streptococci could be demonstrated in the interlobular connective tissue of the liver, and occasionally even in the hepatic vessels. This observation is highly significant in that it forcibly brings home the fact that chronic rheumatoid arthritis is fundamentally a systemic disease, and it explains the transient septicemias that occur intermittently in the course of the infection.

Operative Fusion of Flail Knee Due to Anterior Poliomyelitis.—Cleveland presents an analysis of the end-results of ninety operations for fusion of an unstable knee due to anterior poliomyelitis. The operation was without risk and resulted in no appreciable shortening of the leg. All but a small number of the patients were pleased with the end-results. They were able to discard their braces and walk better. Eighty-five per cent of them had good or excellent cosmetic and functional results. In the younger patients, aged 13 years and less at the time of operation, postoperative deformity-flexion and knock-knee are apt to occur. This is apparently due to gravity and unopposed action of the hamstring muscles on ununited epiphyses. Failure of fusion occurred in but two cases and was easily corrected by operative revision. The best results are obtained in patients with paralysis limited to one leg, but the patients with both extremities involved are greatly benefited.

Osteochondritis Dissecans.—King points out that osteochondritis dissecans occurs primarily in males in the second decade of life and is characterized by death of a special portion of the epiphyseal nucleus and articular cartilage of the knee and elbow joints. Other joints may be affected. The *condition was bilateral in 20* per cent of the author's cases. There is a great tendency to loose-body formation. A clinical history of recurrent locking in a young man, without a history of trauma severe enough to cause a fractured cartilage, suggests osteochondritis dissecans. The diagnosis is rarely made on history and clinical examination alone; roentgen examination is diagnostic. The presence of loose bodies in a knee or elbow joint, whose source is not obvious, suggests a previous osteochondritis dissecans. Radical operation gives a good result in 88 per cent of cases. Slumbering osteochondritis dissecans should be treated conservatively without operation, as spontaneous healing has been demonstrated in these cases. Long-standing cases with many free bodies and severe arthritis may not be cured by operation, because many of the subjective symptoms are due to the accompanying arthritis.

Ostearthritis Deformans and Ostearthritis Deformans Juvenilis.—Lang states that there are no fundamental differences between arthritis deformans of the adult and juvenile arthritis deformans. Both types of the disease originate after damage to the articular and joint cartilage with subsequent loss of its elasticity. This loss of elasticity removes the protection that the normal cartilage affords to the subchondral bone against functional and mechanical influences. As a causative agent for arthritis deformans in adults, the damage to the cartilage, resulting from excessive strains, is of primary importance In juvenile arthritis deformans, direct and indirect traumatic damages to the cartilage and, especially, to the osteochondral junction are held responsible The decisive factor for the progressive course of both types of arthritis deformans is the action of the functional requirements which, acting as a *source of constant irritation, forms the basis for* the progressive character of the disease

Human Capillary Wall During Venous Congestion — Blood samples removed from the arm veins during graded congestion *were compared by Landis and his associates in order to* measure the filtration of fluid resulting from the increased venous pressure The loss of protein through the capillary wall was estimated at venous pressures of 80, 60 and 40 mm of mercury Comparison of hemoglobin readings and red cell counts showed that during venous congestion the fluid is lost chiefly from the plasma The loss of fluid could be detected at venous pressures as low as 20 mm of mercury and amounted to between 0 0 and 2 3 cc per hundred cubic centimeters of blood The amount of fluid lost from the blood was conspicuously greater at higher venous pressures, venous congestion of 80 mm of mercury filtered as much as 19 5 cc per hundred cubic centimeters of blood At a venous pressure of 80 mm of mercury, protein was lost from the blood plasma in an amount indicating that the capillary filtrate contained an average of 1 5 per cent of protein At a venous pressure of 60 mm of mercury, very little protein loss could be detected and the capillary filtrate contained an average of 0 3 per cent of protein The authors describe two cases of edema in which edema fluid was collected during venous congestion The protein content of the edema fluid was 0 39 and 0 09 per cent, indicating that the capillary wall retained approximately 95 per cent of the plasma protein

Blood Uric Acid in Disease —*Jordan and Gaston state* that, with the discovery of the uric acid diathesis in gout, attention was focused on purine metabolism Further studies have indicated that the relationship between uric acid retention and gout is not as simple as at first believed Observers have reported considerable variation in the amount of blood uric acid under normal conditions as well as in diseases other than gout The significance of these observations is not as yet thoroughly undersood *Although mention of gout in the* contemporary American literature is unusual, it has been the authors' experience to find the condition among Chicago patients with greater frequency than was anticipated Whether a similar incidence of gout occurs in other parts of the country would be a matter of interest The amount of uric acid in the blood under normal and pathologic conditions is a matter of basic importance The more accurately the determinations can be made, the sooner will the understanding of purine metabolism approach scientific precision By Folin's method most, if not all, patients with gout will show blood uric acid values above a range which the authors accept as normal The difficulty in diagnosis lies in distinguishing the higher values obtained in conditions other than gout Most of such high values have occurred in the various conditions already known to be at times associated with high blood uric acid

Circulation in Obesity.—Prodger and Dennig studied various phases of the circulation in a group of obese patients who had no demonstrable pathologic changes in the circulatory system, chiefly in their response to mild exercise in the form of walking on a treadmill The results were compared with the results in a group of normal persons The responses of the cardiac output and arteriovenous oxygen differences to exercise were similar in the two groups The chief differences between the two groups were found in the vital capacities, and in the pulse rates, respiratory rates, blood lactic acid changes, oxygen consumptions, and oxygen debts in exercise On the basis of their observations the authors believe that the symptoms which are so commonly associated with cardiac insufficiency and which are frequently observed in cases of simple obesity are not due to an inefficient circulatory response but rather to mechanical and chemical disturbances associated with obesity

Filament-Nonfilament Count.—In a study conducted on 100 patients, Reveno and Berent found that the determination of the percentages of the nonfilamentous and filamentous neutrophils, lymphocytes, monocytes, eosinophils and basophils, by counting 100 consecutive leukocytes, lends itself readily for routine clinical use Much may be learned as to diagnosis and treatment by the use of this method of studying the blood picture Changes in the percentage of the young polymorphonuclear neutrophils (nonfilaments) often precede changes in the physical signs and symptoms as well as total cell count changes In the absence of clinical symptoms, nonfilament deviations from the normal should not be ignored In acute clinical conditions in which the percentage of nonfilamentous neutrophils does not exceed 16, it may be safely assumed that infection is not present A nonfilament percentage of 50 or over is indicative of a poor prognosis Failure of the nonfilament percentage to return to the normal level of from 8 to 16 is a sign of persisting infection The percentage of small lymphocytes is depressed during the acute stage of an infection and rises with recovery, in many instances preceding the onset of convalescence and running parallel with it The authors believe that because of the ease with which it can be performed and because of its great value to the clinician, the filament-nonfilament count should be adopted as a routine procedure in place of the ordinary differential count

Induction of Labor —According to Carmichael, multiparas respond to bougie induction of labor in a slightly greater percentage of cases than do primiparas Multiparas respond to bag induction of labor in a definitely greater percentage of cases than do primiparas The bag is a more rapid method and a more certain method of inducing labor than is the bougie The morbidity in bag induction of labor is slightly greater than in the bougie method The fetal mortality is greater in bag induction of labor than in the bougie method. The incidence of operative intervention is not increased in labors induced by the bougie method The operative intervention incident with bag induction of labor is nearly three times as great as in cases induced by the bougie method.

Chronic Bronchiectasis.—Marvin reports that, although the treatment of bronchiectasis at Fitzsimons General Hospital, Denver, has been conservative, with little experience in the operative procedures now being used at some clinics in the more severe cases, the results have been reasonably satisfactory. Infective foci, especially sinuses, are given early attention. Postural drainage is started at the earliest opportunity and is practiced at least two or three times a day in all cases and as often as every hour in patients severely afflicted. An adjustable table drainage apparatus and a "horizontal bar," or so-called jack-knife drainage method, both of which have their advantages, are used These appliances were constructed at the hospital, the former having been in use for the past six years and the latter during the past year The so-called adjustable table method is rather more comfortable for the patient to use but is not as effective in completely emptying the material from the cavities as the "jack-knife drain" The table requires from twenty to thirty minutes as a rule for maximum results, whereas the bar drain requires but three to five minutes and has the advantage of mechanically compressing the lower thorax. These methods of drainage insure a more complete emptying of the bronchiectatic cavities than leaning over the side of a bed or chair, such as must be practiced by the strict bed patient or by patients in their own homes The important thing is to empty these cavities of secretion as completely as possible and keep them as nearly empty as practicable at all times. Aspiration by means of the bronchoscope is more effective in most cases than the postural method, especially when the secretions in the bronchial dilatations have become very tenacious or so hard and crusted as to require softening by injecting some liquid before suction can remove them.

Perforating Lesions of Large Intestine.—Bargen and Cox describe their observations in fifty cases of perforating lesions of the large intestine In the fifty cases the perforations were all due to diverticulitis or to carcinoma This was confirmed either at operation or at necropsy Symptoms suggestive of perforation were present in all cases; they differed from those common to the various forms of acute, subacute and chronic obstruction of the colon. Clinical, preoperative and historical data were available in only thirty of the cases of diverticulitis and in nineteen of the cases of carcinoma. In the fiftieth case there was a perforating carcinoma at the splenic flexure and a perforative type of diverticulitis with formation of abscess in the descending colon, thus there were fifty-one lesions in the fifty cases. Pain was the most common symptom, being present in twenty-six of the thirty-one cases of diverticulitis, and ranging in degree from slight pain in eight cases to severe pain which could be classified as acute in twenty-three cases. In thirteen of the cases of carcinoma, pain was severe enough to be called acute; in one case the pain was less severe, and in the other six cases pain was not a prominent symptom. Fever was present in twenty-one cases of diverticulitis; it was associated with chills in nine cases. In ten of the cases, the temperature ranged from 100 to 104 F.; in seven of these it was 102 or more. In twelve cases of carcinoma there was a history of fever; in five it was associated with chills. The temperature in these cases was lower; in only three was it more than 101 F. Vomiting was present in five cases of diverticulitis and in two cases of carcinoma An abdominal mass was present and palpable in twelve of the cases of diverticulitis and in eight of the cases of carcinoma. In only one of these was the mass palpated by vagina. In one case of diverticulitis, blood was present in the stools at the time of onset of pain, and in one case "inky" stools were passed. In the whole group there were sixteen vesicosigmoid fistulas, only two of which were caused by carcinoma, the other fourteen originating in the perforating diverticulitis The site of the lesion undoubtedly was a factor in this incidence. In thirty of the cases of diverticulitis the lesion was in the sigmoid, and in only six of the cases of carcinoma was the lesion in the *sigmoid* Additional symptoms in these cases were urinary frequency, dysuria, and the passage of blood, pus, feces and gas by the urethra The duration of these symptoms ranged from two weeks to five years, but in most cases the fistula had been present less than nine months.

Clinical Significance of Melena.—Berkman is of the opinion that, in a surgical exploration for the source of gastro-intestinal hemorrhage in which the bleeding lesion is not found, the abdomen should not be closed until the stomach has been opened and explored for intrinsic lesions In cases of recent hemorrhage, a healed or chronic duodenal ulcer should not necessarily account for the hemorrhage. Infrequently gastro-intestinal hemorrhage occurs from esophageal varices in the presence of cirrhosis of the liver which is impossible to diagnose clinically The hemorrhage is usually manifested by hematemesis and rarely by melena alone. In all cases of recurrent gastro-intestinal hemorrhage, surgical exploration should be done, and in many cases of indeterminate gastro-intestinal hemorrhage it might be extremely detrimental to the patient not to explore surgically because of only one attack of hemorrhage.

Angina Pectoris.—In discussing the surgical treatment of angina pectoris, Howes states that three types of operation are performed; namely, cervical sympathectomy, paravertebral injections of alcohol, and the newer operation of dorsal sympathectomy These operations should be done on carefully selected patients only The rapidly developing type with the threat of approaching thrombosis should be excluded If the patient is in good condition, the more extensive operation of dorsal sympathectomy is the one of choice because of the resulting freedom from the annoying numbness and paresthesia that follow alcohol injections If the patient's condition seems not to warrant so extensive a procedure, injection of the dorsal sympathetic ganglions with alcohol is safe in the hands of the surgeon who is skilful in the technic The author believes it is not yet fully established whether the operation may not, in addition to preventing the sensation of pain, produce some permanent coronary dilatation and have some nitrite-like effect in preventing the ischemia, which is the cause of the pain Recently he had a patient who had four years of freedom from pain as the result of cervical sympathectomy but who had terrific pain when he finally developed thrombosis The author believes that even if some patients die sooner because they do not have the warning that pain gives to overexertion, the mental relief to them to be free from pain and the anticipation of it is well worth a few months of their lives

Significance of Splenomegaly—Personal experience with a group of cases in which splenomegaly was a prominent manifestation has impressed Cohn with the fact that there are several points which should be of great practical value Splenomegalies associated with acute febrile reaction are rarely benefited by splenectomy Splenomegalies associated with lymph node enlargements (Hodgkin's disease, lymphatic leukemia, tuberculosis and syphilis) are not to be considered as surgical cases Gastric hemorrhages are often allowed to cloud the issue and an unwarranted conclusion is arrived at that the disease is primarily in the stomach when in reality it may be secondary to the engorgement of the portal circulation in the case of polycythemia or late Banti's disease and pernicious anemia Secondary anemias are often treated without reference to the etiologic factors If these cases were thoroughly investigated, probably more early splenic anemias would be brought to light Earlier surgical intervention offers the patient more hope for an eventual recovery Hemorrhagic purpura is curable in a spectacular way by splenectomy Serums and calcium salts are of no value in the treatment of true purpura Splenectomy is not to be considered primarily as the treatment for splenomegalies Splenomegaly in some instances is the result of diseases which are curable by splenectomy

Herpes Zoster.—Niles reports that of the sixteen patients with herpes zoster whom he treated with solution of pituitary, eleven were well in an average of eight and one-half days, two were improved, two were unimproved, and in one the result was unknown Of the same number of patients treated by other methods, five were well in an average of eleven days, one was improved, four were unimproved, and in six the result was unknown The injections of solution of pituitary were given intramuscularly every other day With the exception of one case, three injections were sufficient, 0 5 cc was given to elderly patients for the first injection and 1 cc to the middle aged and younger All except four patients received 1 cc at the time of the second and third injection The author used both surgical and obstetric solution of pituitary Although the former is considered to be stronger than the latter, he could not see any difference in the results obtained None of the patients experienced any unfavorable local or general reaction, although several were elderly and suffered from intercurrent diseases This treatment can be given safely to patients and to those suffering from hypertension, cardiac disease or diabetes It is not necessary to delay or discontinue the injections because of menstruation, but they should never be given during pregnancy

Effect of Pregnancy on Sugar Tolerance of Diabetic Persons.—According to Collens and Shack, the dextrose tolerance of a pregnant diabetic woman becomes progressively diminished with advancing pregnancy There occurs in the first few days of the puerperium a transitory period during which the sugar tolerance increases to such an extent that the patient can be considered nondiabetic This period lasts only from one to three days The experience of pregnancy seems to reduce permanently the sugar tolerance of a diabetic woman However, diabetes is not a contraindication to pregnancy alone, for under modern methods of management there are no complications which are intrinsically the result of the diabetic state

Choice of Forceps in Delivery—Dennen states that in a proper case for delivery with forceps the two essential requirements are an accurate cephalic application and traction in the axis of the pelvis A correct diagnosis must be made of the amount of molding, position and station of the head, and type of pelvis Molded heads require a blade with a long, shallow cephalic curve Axis traction diminishes the amount of effort and injury and is desirable in any station of the head The large variety of instruments in use shows that there are no universal forceps In most anterior positions, the Simpson type of blade, with some form of axis traction, is desirable In most posterior and transverse positions, the Kielland forceps seem to be the choice Rotation manually, or with the Barton forceps or the solid blades, may be used in some cases A high transverse head, with a posterior parietal presentation in a flat pelvis, requires the Barton forceps In face presentations, with the chin posterior, the Kielland forceps, and, on aftercoming heads, the Piper forceps offer advantages The author describes new traction curve forceps that may be used in anterior positions of the occiput

Life Tables for Patients with Mental Disease.—Malzberg presents tables showing that the rates of mortality at corresponding ages are from three to six times as great among patients with mental disease as among the general population The higher rates of mortality result in a rapid reduction in the life table populations of the patients with mental disease, 25 per cent dying in from 4 to 6 years, 50 per cent in from 13 to 17 years, and 75 per cent in from 28 to 29 years In the general population, the corresponding periods would be about 32, 48 and 56 years, respectively Such heavy mortality results in a reduction of approximately 18 years and 14 years in the life spans of the male and female patients, respectively There are differerences in the direction of the trends of the mortality rates in the early years, rates among patients decreasing whereas those in the general population increase steadily The male patients have an expectation of life of 19 17 years at 20 years of age, compared with 18 06 years among females At 22 years of age, the expectations are 19 02 and 18 18 years for males and females, respectively In the general population, in 1920, the corresponding expectations at the age of 22 were 41 40 and 42 98 years

Use of Sodium Amytal in Treatment of Psychoses.—Murray and Burns do not feel that sodium amytal affects the fundamental course of psychoses, except in improving the physical condition of the patient by diminishing the activity, and in producing a better contact between the patient and the physician In their series of cases there is only one in which the course of an acute mania seemed definitely shortened The authors feel definitely that the main effect of this treatment is to increase the accessibility of the patient, and that the beneficial results, when obtained, are due to some form of psychotherapy made possible by this The narcosis checks the excitement or removes inhibitions, and enables the patient to get hold of himself to some extent If, at this point, the physician succeeds in establishing a rapport and maintaining it, good results may be expected

Dementia Paralytica—Stanley reports the results in 181 cases of dementia paralytica in which the patients were treated by malaria fever therapy from August, 1924, to November, 1927 According to the hospital records in 1931, fifty-two of these patients on discharge had been considered to show complete remission and fifteen partial remission A complete survey from three to seven years after discharge of the patients with complete or partial remission showed that now only seventeen cases could be considered complete remissions Eight patients had died, three had been returned to a mental institution, and twenty could not be located In the seventeen cases of complete remission from three to seven years after discharge, eight of the patients had had follow-up treatment with tryparsamide The author concludes that many patients discharged from the hospital as in a condition of complete remission tend to show relapses, and that one can get the best results by combining malaria and tryparsamide therapy One should also make some provision whereby one is sure that these patients discharged from the hospital will be properly supervised and treated over a period of at least three years, as it is pretty generally accepted that cases showing positive serologic changes, though clinically a remission, tend to relapse unless treated

Immunization Against Diphtheria.—Gaede records results obtained with diphtheria toxoid in the active immunization against diphtheria and compares them with those obtained with toxin-antitoxin. In 103 Schick-positive children, three injections at weekly intervals of commercial toxin-antitoxin produced 68 per cent negative Schick reactions from three to six months after the final injection. In 504 Schick-positive individuals, two injections of diphtheria toxoid at intervals of from three to four weeks gave a negative Schick test from two to three months after the last injection in 86.2 and 93.1 per cent of the cases. In 112 preschool children, two injections of diphtheria toxoid produced a negative Schick test in only 76 per cent. The reason for such a low immunity response in this group has not been definitely determined. The advantages of diphtheria toxoid over toxin-antitoxin in the prophylaxis of diphtheria are threefold: (1) the larger percentage of negative Schick tests obtained after the injections of the material, with a greater rapidity of establishing this immunity; (2) the avoidance of possible serum sensitization in the subject immunized, and (3) the greater stability of the preparation and its absolute innocuousness. The disadvantage of diphtheria toxoid, compared with toxin-antitoxin, lies chiefly in the questionably more frequent occurrences of local and general reactions resulting from the injections. This, however, can be obviated by excluding those individuals who show a strong pseudoreaction to the Schick test and those who are positive to the intradermal injection of the diluted toxoid. The author regards as essential the routine employment of the Schick test two or three months after the completion of the immunization. Any program of diphtheria prevention must include and especially emphasize the necessity of immunizing the preschool child. In conclusion the author states that the use of diphtheria toxoid as an immunizing agent in the prophylaxis of diphtheria is highly recommendable, and, in children, is to be preferred to toxin-antitoxin.

Peptic Ulcers and Interbrain.—The attempt to find a reasonable explanation for the acute perforative lesions affecting the esophagus, stomach and duodenum, which in three instances caused early fatality after operations for cerebellar tumor, led Cushing not only to a review of the extensive literature on the neurogenic aspects of ulcer pathogenesis but also to certain experimental observations that strongly suggest the presence in the diencephalon of a parasympathetic center. From this center, apparently tuberal in situation, fiber tracts pass backward to relay with the cranial autonomic stations of midbrain and medulla, of which the vagal nucleus is by far the most important because of its influence on the activity of the lungs, heart and upper alimentary canal. Experimental lesions anywhere in the intracranial course of these fiber tracts from anterior hypothalamus to vagal center, presumably from parasympathetic stimulation (or possibly from vagal release due to sympathetic paralysis), are prone to cause gastric erosions, perforations or ulcers. Intracranial injuries and diseases affecting these basilar regions of the brain are known to be accompanied by ulcerative lesions of the upper alimentary canal. It is reasonable to believe, therefore, that the perforations following the cerebellar operations forming the basis of the author's study were produced in like fashion by an irritative disturbance either of fiber tracts or of vagal centers in the brain stem. The author points out that those favorably disposed toward the neurogenic conception of ulcer have in the course of time gradually shifted the burden of responsibility from the peripheral vagus to its center in the medulla, to the midbrain, and now to the interbrain, newly recognized as a highly important, long overlooked station for vegetative impulses easily affected by psychic influences. So it may easily be that high strung persons, who incline to the form of nervous instability classified as parasympathetic (vagotonic), through emotion or repressed emotion, incidental to continued worry and anxiety and heavy responsibility, combined with other factors such as irregular meals and excessive use of tobacco, are particularly prone to have chronic digestive disturbances with hyperacidity often leading to ulcer—effects wholly comparable to those acutely produced by irritative lesions experimentally made anywhere in the course of the parasympathetic system from the tuberal center to its vagal terminals. While this conception of the etiology of ulcer does not account for all ulcerative processes under all conditions, it offers a reasonable explanation of the majority of them and is in accord with the personal experience of most victims of chronic recurring ulcer. This, briefly, is as near as one can come, with the data at hand, to an interpretation of the neurogenic origin of peptic ulcer and an explanation of its existing prevalence.

Relation of Pyogenic Arthritis to Osteomyelitis.—Bisgard reports that of 217 cases of pyogenic osteomyelitis there was associated arthritis in 41 cases, an incidence of 23.5 per cent. Of these 51 cases, 42 (19.3 per cent) arose by direct extension from an adjacent diaphyseal infection. The large weight bearing joints constituted 92.5 per cent of this group. In 9 cases (4.1 per cent) the joints appeared to have become involved by blood-borne infections, presumably from remote foci of osteomyelitis. However, there may have existed at some time a small undiscovered lesion in the adjacent bone, and the joints may represent the end-result of an abortive osteomyelitis. The seriousness of this complication of osteomyelitis was measured in this analysis by the end-results of the joint damage alone. Only 13.2 per cent of joints infected by direct extension regained a good range of motion; 65.2 per cent became ankylosed, and the remaining 22.6 per cent suffered varying degrees of functional limitation. A comparison of these end-results with those resulting from hematogenous infection, in the small series analyzed, suggests that less joint damage is produced by the latter type. In this group ankylosis occurred in 44.5 per cent and a good range of motion was preserved in 33.3 per cent of the cases.

Pancreatic Lithiasis.—According to Ackman and Ross, pancreatic lithiasis, of which they report a typical case, has been reported only slightly over 100 times. Whereas most of the earlier cases reported were from necropsy observations, in the majority during the last fifty years successful operations have been performed. Epigastric pain of both dull and colic-like nature is the commonest symptom, but unfortunately there is no consistency in radiation. Steatorrhea and diarrhea attract particular attention in the symptomatology. These symptoms, together with the occasional finding of calculi in the feces, make the examination of the stools of great importance. Glycosuria of true diabetic character is a frequent observation late in the condition. It appears to be coincident with extensive destruction of the islets of Langerhans by the fibrotic pancreatitis that occurs with this condition. Jaundice occurs often enough to lead frequently to the incorrect diagnosis of cholelithiasis. Correct clinical diagnosis is difficult, and though the roentgen ray is of great value it may not be conclusive, while even at operation stones may be missed, particularly if single, A peculiar crepitus when multiple stones are present has been described Surgical treatment has yielded gratifying results from every standpoint. The mortality rate is less than 6 5 per cent. When properly treated, diabetes mellitus does not constitute a contraindication to operation. Characteristic pathologic changes occur in the parenchyma of the gland, beginning as a chronic interlobular pancreatitis and gradually involving the whole gland in a fibrotic process, with resultant atrophy and loss of parenchyma. The islets of Langerhans are last to be involved. The calculi are composed for the most part of calcium carbonate and calcium phosphate. These observations are suggestive of an inflammatory etiology Associated pulmonary tuberculosis has been noted in a number of cases The incidence of this is, however, probably not more than might be expected in diabetes mellitus generally.

Treatment of Depressed Fractures of Vault.—Coleman points out that the prevention of epilepsy and headache following depressed fractures of the skull is more likely to succeed if, in addition to the elevation or removal of depressed fragments, such treatment of the injured brain is carried out as will limit the amount of cortical scar tissue The treatment of the local brain injury underlying the depressed fracture is of greater importance than the mere elevation of the depressed bone. Compound fractures of the vault require early operation to prevent infection of the brain and to minimize the late bad effects of the local injury The author believes that the principles of surgical treatment of compound fractures of the vault for prevention of infection should be extended to certain fractures of the base, in which there is a communication between the meningeal spaces and the sinuses, as shown by a continued cerebrospinal fluid leak or air remaining in the brain tissues and cerebrospinal fluid spaces.

Amyoplasia Congenita.—Sheldon points out that the name "multiple congenital articular rigidity" sums up the leading clinical characteristics of amyoplasia congenita, once seen the recognition of other cases should be easy. It is to be remembered that the position in which individual joints may be fixed may vary in different cases, as may the range of movement The only other disease with which it might be confused is spastic diplegia due to lesions of the nervous system, but in that condition the stiffness of the limbs can be slowly overcome by passive means and there is no actual fixity of the joints. Also the spasticity relaxes under anesthesia Cases presenting fixed extension of the elbows, pronation of the forearms, and flexion of the wrists, bear a resemblance to Erb's type of brachial palsy, but in the latter condition the arms are flail and there is no ankylosis of joints. The rigidity is greatest at birth; it may persist undiminished, but by constant efforts at passive movements carried out over months or years, some increase in the range of mobility may be obtained. Major orthopedic operations have been undertaken in some of the cases with apparently good results, particularly in the cases of fixed flexion of the knees

Plasma Phosphatase in Rickets and Scurvy.—According to Smith and Maizels, the chemical changes in rickets and scurvy are to some extent contrasting, as might be expected from the other pathologic changes in these conditions. In rickets there is excessive proliferation of cartilage cells, increased vascularity, and the formation of a wide zone of osteoid tissue The high phosphatase found in rickets is probably derived from these hypertrophic cartilage cells and osteoblasts which Robison has shown to be the source of the enzyme, and its presence in increased quantity supplies one of the factors essential for ossification. In scurvy, on the other hand, the picture is one of cessation of growth, and ossification is in abeyance The cartilage cells are disorganized and are fewer in number and smaller in size than normal. Hence, in the acute stage there is neither the source nor the need for the production of phosphatase. This holds good also in cases with subperiosteal hemorrhage before calcification begins. With the administration of antiscorbutic vitamin, growth begins again and calcification of any hemorrhage present proceeds; the cartilage cells become active and the plasma phosphatase rises, corresponding to a probable increase in the secretion of phosphatase in the bone. The observations in cases of fractures agree with these conclusions The author found the average normal plasma phosphatase in infants under 1 year to be 0 23 unit (range 0.10 to 0 27). In the second year the figures were slightly higher, averaging 0 24 unit (range 0.11 to 0 33), while the phosphatase content in older children up to 12 years of age averaged 0 17 unit (range 0 12 to 0.2). The plasma phosphatase is increased in active rickets, the degree of elevation corresponding to the severity of the disease. The average phosphatase in nine cases of uncomplicated rickets was 0.75 unit, with a range of 0 3 to 1.4. Whereas the blood calcium and phosphorus rapidly returned to normal with treatment, the decline in the phosphatase was much more gradual, and normal values were not regained until the healing process was complete The phosphatase was found to give low normal figures in the acute stage of scurvy whether subperiosteal hemorrhages were present or not. A rise of the phosphatase appeared coincident with the onset of calcification of the hemorrhages and this fell again with the absorption of these calcified areas. The plasma phosphatase was normal in cases of fracture immediately after the injury but rose at the same time as the callus appeared and fell to normal when the bone was completely healed.

Acute Otitis Media in Infancy.—Asherson states that in an infant the tympanic membrane may remain of apparently normal color and yet have pus behind it. A temperature of over 100 F. with an unruptured tympanic membrane, during an attack of acute otitis media, even though such a figure has been reached only once during the illness, indicates the presence of a suppurative lesion, demanding myringotomy without delay. Even if the patient is not seen until a late stage of the attack when only a mild degree of fever is present, the same conclusions should be drawn if there is a clear history of an earlier temperature of over 100 F. The presence of high fever in an infant, even in the new-born, should lead to a suspicion of acute otitis media calling for a careful examination of the ears. In cases of infantile gastro-enteritis the ears should be kept under the observation of the otologist. If myringotomy reveals pus, the antrum should be drained.

Alteration of Circulation of Brain by Surgery in Diseases of Central Nervous System.—Royle says that it is a well known principle underlying the physiology of the central nervous system that hyperactivity accompanies slight degrees of asphyxia or anoxemia. The operation of this principle suggested itself to him when he had observed the results following a sympathetic thoracic trunk section on a patient with extensor spasm. He was demonstrating the ipsilateral effects showing how the ipsilateral forearm fell when released from the perpendicular position, when to his surprise the contralateral forearm fell much more rapidly. The operation of sympathetic thoracic trunk section profoundly alters the cerebral circulation, and the result he had observed was explained by the change in circulation in the opposite side of the brain. It then occurred to him that in paralysis agitans, spastic hemiplegia, and other conditions, he had been operating on the side of the manifestation of the lesion instead of on the side of the lesion in the brain. This reflection opened up a new aspect of the surgery of the sympathetic nervous system—that of changing the reflex activity of the central system by altering the blood supply of the brain rather than attempting to change its peripheral manifestations by cutting peripherally directed rami of the sympathetic nervous system. The author presents an account of the technic and results of sympathetic thoracic trunk section in various surgical operations and laboratory experiments.

Treatment of Fractures.—Jones predicts that in consequence of the advances made in the treatment of fractures the "massage" departments of hospitals will undergo a great transformation during the next few years. A patient with a fractured limb can be persuaded that it is safe to use it only if he is taught occupational activity under supervision. In the author's physical therapy department at the Liverpool Royal Infirmary the number of patients who are actually being massaged is reduced to a negligible minimum. But every patient goes into the department as soon as roentgenograms have shown that the fracture is perfectly reduced. The man whose Pott's fracture was reduced yesterday is today being taught to walk. The woman who sustained a Colles fracture yesterday is today learning to make beds and peel potatoes. As far as possible, individual occupational activity is maintained throughout the period of immobilization. The patient with the fractured spine, whose trunk is encased in plaster, is taught exercises for the erector spinae, which are far more effective than faradic stimulation, even if such were possible. Every patient whose knee joint is immobilized, whether he walks or not, is taught tonic exercises for the quadriceps, and if a patient is due for admission to a hospital for a knee operation he is first taught quadriceps drill until he is so expert in his exercise that he can practice it from the day of operation onward. In short, modern treatment anticipates the complications of muscle wasting, joint stiffness and mental fear, and instead of treatment being prescribed after these conditions have developed, steps are taken to prevent them from appearing.

Prognostic Value of Spinal Anesthesia in Vasospastic Diseases of Lower Limbs.—Telford and Stopford say that in any case of thrombo-angiitis obliterans there is the element of vasospasm, which can be relieved by cord sympathectomy, and there is the element of thrombosis, on which operation is useless. The propriety of operating can be decided only by an endeavor to estimate the relative amounts of spasm and thrombosis. The authors feel that this can best be done in the lower limbs by a spinal anesthetic. The method need involve no trouble for the patient, as the spinal injection is given on the operating table and the operation can be undertaken or abandoned on the observations given by the thermometer within five minutes of the injection. These advantages render this method much more attractive, safer, and quicker than those involving the intravenous injection of substances which commonly cause the patient discomfort for some time. Furthermore, the response to a spinal anesthetic gives an accurate record of what can be expected from sympathectomy, while the rise in surface temperature induced by fever only approximates roughly to that following excision of the sympathetic supply.

Action of Ergot Preparations on Puerperal Uterus.—According to Moir and Dale, the liquid extract, and the solid extract of ergot, of the 1914 British pharmacopeia, both show great activity in stimulating contractions in the puerperal uterus. Defatted ergot powder has a similar action. The keeping properties of the extracts appear to be good. Different samples of ergot vary in their activity. The effect of the drug comes on with remarkable suddenness and may appear within four minutes of oral administration of the liquid extract. There is an increased tone of the uterus to an extent much greater than that seen with other oxytocic drugs. In these and other respects the ergot extracts act in a far different manner from the purified alkaloids ergotoxine and ergotamine. Histamine and tyramine, given in reasonable dosage by the mouth, have no effect on the puerperal uterus. Histamine given by intramuscular injection has slight effect on the uterus but may produce undesirable symptoms. There is reason to believe that the characteristic and traditional effect of ergot is due to a substance as yet unidentified.

Laboratory Diagnosis of Plague Infections.—De Smidt points out that, in the human subject during life, laboratory diagnosis of plague infections depends on either microscopic or cultural examination, or both together, of the following materials: (1) lymph node substance obtained by needling of a bubo; (2) blood withdrawn from a vein for culture, or merely a drop of blood for a slide, and (3) sputum. Examination of lymph node substance is of course restricted to bubonic cases or those in which enlarged lymph nodes can be found. Blood culture is not very likely to yield growth of bacilli except in the markedly septicemic type of case, and then the positive result may be obtained only perhaps two or three days after the patient's death. Microscopic examination of an ordinary blood slide may give a rapid diagnosis but again is likely to be positive only in a severe septicemic case. Microscopic examination of sputum may afford a quick and certain diagnosis in a septicemic case with bronchopneumonic involvement of lung in which differentiation is to be made from common pneumonia. The author describes in detail these various forms of laboratory diagnosis.

Physiologic Leukocytosis.—Martin examined the diurnal variation of the leukocyte count during rest and found that the counts are steadiest and at a minimum when the patient's condition approximates most nearly that of absolute physiologic rest; that they rise with increase in the mental and physical activity of the subject, and that they tend to rise in the late afternoon and early evening, this being regarded as the period of greatest activity. The effect of exercise on the peripheral blood was investigated. The total leukocyte count exhibited a rise varying from 15 to 48 per cent of the resting value, and it returned to normal after about thirty minutes' rest. Further exercise then produced another rise in the count similar in type and degree to the first. The rise in the total count was due to an increase in the number of all types of cell, but the lymphocytes showed the greatest increase. The hypodermic injection of epinephrine is followed by a leukocytosis in which all types of cell show an increase, but that of the lymphocytes is most marked. It is similar to the leukocytosis following exercise, and the author advances the theory that the latter is produced by autogenously secreted epinephrine. The cells that cause the leukocytosis arise from two sources. The lymphocytes are in all probability derived from the lymph nodes which contract under the influence of the epinephrine, and the granular cells are washed out of the bone marrow by the increased blood flow due to cardiac stimulation by the epinephrine.

Sympathetic Vasodilators and Epinephrine.—Burn describes experiments in which he demonstrated the existence of vasodilator fibers in the lumbar sympathetic chain of the dog. He also demonstrated that both the magnitude of the vasodilator response and the magnitude of the vasoconstrictor response to sympathetic stimulation are dependent on the amount of epinephrine in the circulating blood.

Reactions of Eye to General Disease.—Williamson-Noble points out that the changes in the eye associated with high blood pressure are of great clinical importance. The retina is morphologically a portion of the brain and, from the clinical standpoint, it is the condition of the cerebral circulation which most closely concerns one in cases of vascular disease. In the second place, the eye is the only portion of the body where the cerebral vessels are, so to speak, open to inspection; and the dioptric arrangements are such as not only to render the vessels visible but actually to magnify them 14 diameters. It is not surprising, therefore, that the ophthalmologist, by his routine examination of the fundus, is often the first person to discover the presence of vascular disease. The retinal circulation is a little unusual in that the larger vessels, although morphologically arteries, resemble arterioles in the thinness of their walls and the paucity of their muscular layer. The first and most important change, to the author's mind, is localized variation in caliber. The condition is not by any means conspicuous and, unless carefully sought, may be overlooked. The author has seen definite nipping of the superior temporal vein by the artery in perfectly healthy children, and he has seen no nipping at all in cases in which the systolic blood pressure was over 200 mm. of mercury. There was, however, a telltale diminution in caliber of the inferior nasal and the superior temporal arteries. In addition to the localized variations in caliber of the retinal arteries there is often a generalized attenuation. The vessels so affected are often straight, instead of being curved, as in the normal eye, and usually give off their branches at an acute angle. These attenuated vessels are often found to have walls that are thinned rather than thickened. Nipping of the vein alone is not sufficient ground for the diagnosis of retinal arteriosclerosis and, since the sclerosis is essentially patchy and may not affect the portion of artery crossing the vein, its absence is also of no great significance.

Asbestosis Body.—Gloyne states that from the presence of the asbestosis body in the sputum the following deductions can be made: 1. Since these typical bodies have not been found in any other disease, their presence is an indication of exposure to asbestos' dust. 2. The fact that the bodies have not been found in asbestos dust implies that their formation is the result of some tissue reaction in the body—probably a colloidal reaction in which the iron plays a part. 3. The presence of asbestosis bodies in the sputum means that asbestos fibers have been present in the lung for many weeks at least. 4. The presence of the asbestosis body implies a tissue reaction to the fiber, but it does not necessarily follow that this reaction is accompanied by fibrosis. On one occasion the author found fine connective tissue fibers in sections of a guinea-pig as early as twelve days after subcutaneous inoculation of asbestos fibers, but the amount was minute. A heavy dose of fibers would be needed—and even then years might elapse—before the fibrosis was sufficient to be detected by physical signs or roentgen examination or to produce dyspnea. It would be unsafe, therefore, to accept the presence of the asbestosis body as undeniable evidence of fibrosis; all one can say at present is that the asbestosis body is an expression of tissue reaction of the nature of a benign irritant, and that fibrosis of an appreciable extent may or may not be a part of that tissue reaction.

"Slow Dulcite Fermenters" in Summer Diarrhea.—Nelson reports that the examination of large numbers of children in Melbourne suffering from diarrheal disease during the summer months has revealed a type of dysentery bacilli characterized by the slow fermentation of dulcite in peptone water sugar fermentation tubes. This strain has been found repeatedly since 1928 in the stools of children suffering from diarrheal diseases. During the summer of 1930 to 1931, it was isolated from the stools of 9 per cent of 122 patients with diarrheal disease examined in Melbourne. This strain resembled Bacillus flexneri in many ways but differed from it in (1) the appearance of the colonies on agar plates, (2) fermentation of dulcite, (3) no formation of indole, and (4) serologic reactions (agglutination and absorption of agglutinins). The type of illness affecting the children in whom it was found was a milder form of dysentery than that caused by Bacillus flexneri, for there were no deaths; while of the patients suffering from dysentery due to Bacillus flexneri, 16.6 per cent died. Pathogenicity for human beings tends to be confirmed by the development of agglutinins in patients' serums and by the absence of the well recognized types of dysentery bacilli from the stools. Some evidence of pathogenicity for laboratory test animals is given.

Observations on Gastric and Duodenal Ulcers.—Moynihan calls attention to the fact that it is far too often the custom to speak of gastric and duodenal ulcer as one and indivisible in causation, symptomatology and treatment. This is a grave mistake. The two diseases occur in different types of individual. The chemical constituents of the gastric juice are as a rule quite dissimilar; a close analysis of the clinical symptoms reveals subtle, but often quite clearly recognizable, distinctions; perforation and hemorrhage do not occur with equal relative frequency; carcinoma is not an uncommon terminal result in gastric ulcer—it occurs in less than one in a thousand cases of duodenal ulcer. The pylorus forms a sharp line of division between the two and is rarely transgressed by a duodenal ulcer, almost never by a gastric ulcer. The author believes that it is important to distinguish between acute and chronic gastric ulcers. Acute ulcers are commonly if not invariably associated with toxemia; an infection in the mouth, on the skin, in the appendix or elsewhere may be the primary cause of those minute shallow erosions of the stomach or duodenum which cause dyspepsia, hemorrhage or perforation. Hemorrhage and perforation, though themselves acute, are with few exceptions the evidence not of acute but of chronic ulceration which has assumed fresh activity. In a series of gastric ulcers observed over a period of twelve years it was found that in sixty-one cases in which death occurred from perforation, the ulcer was of the chronic type in sixty; in fourteen cases in which death occurred from hemorrhage, the ulcer was of the chronic type in thirteen. In the acute case the ulcer was a terminal condition associated with advanced disease, and hemorrhage was not the determining cause of death. In a similar series of cases of duodenal ulcer during the same period, this truth also held good; twelve deaths from hemorrhage all occurred in cases of chronic ulcer; in 117 deaths from perforation there were 109 cases in which the chronic ulcer had given way; in twelve cases acute ulcer was present; so that there were four cases in which both acute and chronic ulcers were found; in every one it was the chronic ulcer that had perforated.

Infections of Hands and Fingers.—Fraser summarizes the principles of treatment of nail infections as follows: Unless pus formation exists, it is a mistake to incise the parts; no real benefit is achieved, but on the contrary tissue spaces are opened up which may lead to an extension of infection. In the early stages, therefore, he contents himself with such conservative measures as the application of a narrow congestive bandage around the finger base, and the application of heat to the part through the medium of hot finger baths or hot fomentations, the former for preference. It may be that by these means the formation of pus is avoided. As soon as suppuration has occurred, it should be released by an appropriate incision. The part should be incised in such a way as to secure a sufficiency of drainage and yet preserve the future function of the tissue. In practice the detail is as follows: Suppuration at the eponychium is incised by a flap incision so designed that the integument overlying the nail root is uplifted so as to permit the introduction of a narrow rubber tissue drain. Pus formed at the nail edge is released by an incision parallel to the long axis of the nail but so placed as not to damage the protective cornified ridge. If suppuration is extending beneath the nail into the nail bed it is rarely necessary to remove the nail plate. Pus formed in this situation extends slowly because of the physical resistance offered by the tissues, and if the progress of events is carefully observed a local release of pus is secured while the suppuration is still confined to a small area. To remove the entire nail plate while the pus formation is limited is a harmful and barbarous procedure, for not only is it unnecessary but it exposes fresh tissue to infection and may result in permanent disfigurement of the finger tip. In such cases the author removes by means of small, strong, sharp-pointed scissors that portion of the nail plate which overlies the pus collection. The after-treatment of nail infection implies the continuance of hot antiseptic finger baths, of hot fomentations in the intervals of bathing, and of congestion. As soon as the infection has subsided a mild astringent antiseptic, such as acriflavine hydrochloride 1 : 1,000, is an appropriate dressing.

Seasonal Hay Fever.—According to Knott and his associates, rhinologic opinion is sharply divided on the question of the importance of the nasal factor in the group of diseases represented by hay fever, asthma, and chronic vasomotor rhinitis. An increasing body of opinion favors the view that sinusitis, when present in these conditions, is purely a secondary effect of the hypersensitiveness and repeated attacks of edema, and bears no causal relationship to it. Others regard pathologic conditions of the mucous membrane and sinuses as important predisposing factors to the development of hypersensitiveness. Certainly it is obvious that a nose already obstructed by a badly deflected septum or by the congestion of chronic infection will withstand the edema of hay fever with more difficulty than a normal nose, and that a chronic irritation from infection may increase the local reaction and prevent successful desensitization.

Indigestion.—Patterson states that indigestion may follow faulty habits, organic disease of the digestive tract or functional derangements of its secretory or motor mechanisms. Perhaps the commonest cause in everyday life of discomfort after meals is the bad habit of hurrying over meals, chewing the food incompletely or swallowing large boluses. Gulps of air are swallowed with hurriedly taken food and drink, and give rise to distention and flatulence. The practice of taking solid food and fluids separately is a simple but often successful means of prevention. The teeth should be examined, and those found to be painful or infected removed and adequate dentures supplied. Pus swallowed from infected teeth and gums, tonsils and accessory nasal sinuses will readily set up an atonic gastritis leading to indigestion. Alcoholic gastritis may be diagnosed readily when kept in mind. A common cause of indigestion nowadays is the recourse to acetylsalicylic acid and other coal-tar drugs for headaches, muscular pains and fatigue.

Minor Ailments of Feet.—Dodd concludes his review of minor ailments of the feet by mentioning the condition of pied forcé, which manifests itself by chronic discomfort and later moderate swelling over the shaft of the second or third metatarsal. Clinically and roentgenologically it may strongly suggest a fracture with a very mild reaction. After overuse of feet unaccustomed to strain, as in army recruits and enthusiastic hikers, a fracture of the shaft occurs quietly, without particular incident or pain. Early during the war, a battalion in France had two hundred men "confined to barracks" by "hysterical flat feet." A surgeon who saw some of them advised roentgen examination, and ultimately numerous cases of pied forcé were revealed, caused by long route marches with full packs during intensive training. Treatment consists in supporting the feet adequately in a stout plaster or boot until roentgen examination shows sound bony union. This condition may account for a few of the cases of obstinate pain in the feet, which are cropping up at present as the result of "overhiking."

*Supramesocolic Deformities of Duodenum in Form of "M." J. Quénu *and C. Jacquelin.—p. 601.*
Physiologic Studies of Stomach Following Ligation of Principal Arteries. E. Brenckmann.—p. 625.
Acid-Base Equilibrium of Urine. Chatron.—p. 637.

Deformities of Duodenum.—Quénu and Jacquelin designate as M shaped duodenum that deformity of the mobile duodenum which has been variously described as redundant duodenum, curved duodenum, angulated duodenum and so on, and which seems to result from the lengthening and sagging of the second portion of the duodenum in its supramesocolic segment. They report seven cases which illustrate different stages in the evolution of the deformity ranging from a simple duodenal inflexion forming an M, without localized dilatation or stasis in the joint of the inflexion, to the stage in which dilatation is at a maximum and the two median downstrokes of the letter form a large basin which empties into the remainder of the duodenum only by regorgement. In most of the cases there existed together with the deformity and disorders of the supramesocolic transit a dilatation immediately above the mesenteric crossing and a certain degree of stasis at this level with exaggerated antiperistalsis. A lengthening of the stomach with ptosis of the lower portion was also found in most of the cases. Discussing clinical manifestations, the authors remark the early appearance of digestive disturbances in adolescence or even childhood, which speaks in favor of the congenital nature of this deformity. The dyspeptic disorders, however, almost never present an acute character as in duodenal stenosis of rapid formation. They call attention to the difficulty experienced by the surgeon in finding exactly the deformity indicated by roentgenography. Medical treatment, such as employed in incomplete stenosis, usually suffices for the cure of M shaped duodenum. Surgical intervention is indicated clinically by aggravation of pain, frequent vomiting, paroxysmal crises, and decline of the general condition, and roentgenologically by the degree of sinking and dilatation of the duodenum and above all by the severity of the duodenal and retrograde gastric stasis. The intervention consists in suppression of the duodenal stasis by transmesocolic duodenojejunostomy. If the duodenal stasis is accompanied by gastric stasis, gastrojejunostomy must also be undertaken. The latter should be performed first and at a higher point on the jejunum than the duodenojejunostomy.

Pseudodementia Paralytica Following Carbon Monoxide Poisoning.—Meyer reports the history of a woman in whom three weeks after acute poisoning with carbon monoxide there developed, following an initial agitation, a condition resembling a syphilitic dementia paralytica, which took an acute course and ended fatally within four weeks. The pathogenesis of the dementia paralytica-like course of carbon monoxide intoxications has not been explained as yet. It has been assumed that the primary cause of the process is a nutritional disturbance, but why some cases end in recovery and others show progressive exacerbation even after they first manifest a tendency to a favorable outcome is still unexplained. The theory that the primary nutritional disturbance leads to chemical changes with varying toxic effects only describes the lack of knowledge. However, the author calls attention to investigations which revealed that the primary process in carbon monoxide poisoning is a paralysis and dilatation of the vessels. This leads to stasis of the blood that is impaired by the absorption of carbon monoxide. Secondarily there develops a disintegration of nervous elements, as could be ascertained in cases with slow lethal course. Most susceptible seem to be the cells of the *pallidum*; then follow the layers of the cerebral cortex and the cerebellar cortex. The scars in late cases resemble perivascular foci of obliteration and gliosis as found in arteriosclerosis. This seems to indicate that perhaps existing arteriosclerotic or syphilitic vascular changes predispose to a severe course of carbon monoxide poisoning.

Cutaneous Symptoms in Sodium Chloride Retention.—Jäggi relates that he observed several patients with acute or with progressive cutaneous symptoms such as urticaria, eczema and prurigo, in whom serologic examination revealed a retention of sodium chloride or of chloride, but the protein content and the urea content were not increased. The main reason why these patients asked medical advice was intense and sometimes unbearable itching which was especially severe toward evening. The sodium chloride retention was accompanied by water retention, and especially noteworthy was the complete failure of the perspiratory function. The blood pressure was normal in all patients, and the composition of the urine was likewise normal. A diet deficient in sodium chloride and mostly lactovegetarian effected a rapid disappearance of the manifestations. That the intake of protein does not have an injurious effect was demonstrated in an experiment. Since the dietary treatment is simple and gives rapid results, other measures are not necessary; but the author thinks that diuretics may accelerate the therapeutic effect.

*Morphologic Aspects of Endocrine Organs Under Influence of Sudden Hyperglycemia. M. Mattioli.—p. 859.
Practical Utility of Complemental Operations of Hysterectomy in Cancer. F. Lobello.—p. 867.

Morphology of Endocrine Organs Under Influence of Hyperglycemia. — Mattioli reports his observations after injecting dextrose and epinephrine into dogs. Histologic examination reveals an increase in the number and size of the islands of Langerhans in the pancreas, a great prevalence of acidophilic cells in the anterior lobe of the hypophysis and extreme hyperplasia in the cortical portion of the suprarenal and in the parathyroid. There are few or no histologic modifications in the medulla of the suprarenal and in the thyroid. Except for a mild hyperplasia in the endocrine part of the pancreas, the modifications do not occur when insulin is administered in addition to the dextrose. This all the more confirms the concept of the great importance of the islands of Langerhans in glycoregulation. The author concludes that the endocrine tissue of the pancreas is the principal factor in the mechanism of glycoregulation; the participation of other endocrine organs should always be considered as secondary in relation to the endocrine portion of the pancreas.

Ascending Neuritis Treated by Sympathectomy.—Diez states that ascending neuritis is cured immediately and permanently by sympathectomy. He reports a case of typical ascending neuritis of the left arm, of twelve years' duration. The patient obtained immediate relief and permanent recovery by the resection of the stellate and middle cervical ganglions, with resection also of the ramus internodialis corresponding to these ganglions. The patient regained her working capacity almost entirely. When she was observed a year and a half after the operation had been performed, the satisfactory results still persisted. The author's case is the fifth reported in the literature in which ascending neuritis has been cured by an operation on the sympathetic nervous system. The author discusses the etiopathogenesis and physiopathology of the disease. The symptomatology and evolution of ascending neuritis are well known. Although there are not, up to the present time, precise data on the etiopathogenesis of the disease, the theory of a chronic and attenuated infection, progressing centrad to greater nerve trunks, through the neurilemma, proves to be correct. The theory that ascending neuritis is a sympathetic neuritis is based on the assumption of a peripheral sensory action of the sympathetic nervous system, which action is not proved. If the sympathetic nervous system had a direct action on the peripheral sensibility, the cutaneous hyperesthesia which follows ganglionectomy would affect the entire member corresponding to the suppressed sympathetic fibers, which is not the case. The sympathetic fibers, because of their relation with the spinal nerve fibers, are in some form involved in the production of the painful syndrome of ascending neuritis, in the determination of which, however, they do not have any part. The painful syndrome is a reaction of the spinal nerve fibers against the injury of their roots by a schwannoma formed at the distal end of the resected rami communicantes. The cutaneous hyperesthesia is entirely radicular. Since the cutaneous hyperesthesia is not of a peripheral but of a radicular origin, it is only logical to assert that the spinal roots also determine the pain provoked by the mechanical stimulation of the ganglions of the sympathetic nervous system. In other words, the peripheral pain caused by the stimulation of the ganglions of the sympathetic chain is the typical reproduction of the phenomenon of cutaneous irradiations of visceral pain described by Head and Mackenzie. The term sympathetic neuritis is improperly used, since it has been proved that ascending neuritis is a neuritis of the spinal system. The resection of the stellate ganglion cured the ascending neuritis by an indirect mechanism, by the production of vasodilatation, which (by increasing the circulation in the affected member) has a favorable action on the inflammatory condition of the neurilemma, since increased circulation has in general a favorable action on inflammatory conditions. The author says that, in order to make the indications for operation on the sympathetic nervous system more precise, it is advisable to obtain a thorough knowledge of the normal physiology of the sympathetic nervous system as well as of the physiopathologic changes caused by sympathectomy.

Persistent Complement Fixation and Cure of Gonorrhea.—Fröhlich and Jordan report studies which show that a positive complement fixation reaction frequently persists for several years and that therefore it does not necessarily prove the existence of a latent focus of gonorrhea. The practical conclusion they arrive at is that gonorrhea can be declared cured only on the basis of a bacteriologic examination. If several bacteriologic tests of the various secretions have given negative results, a positive seroreaction may be disregarded. However, if there is some doubt about the exactness of the bacteriologic tests, a positive seroreaction facilitates the recognition of cases not yet completely cured. In these cases a gonorrheal prostatitis frequently exists, but the authors think that gonorrheal foci of a different localization are rarely detected by the complement fixation reaction. They consider it advisable to subject every gonorrhea patient who has had a prostatitis to a complement fixation test six months and twelve months after completion of the treatment; if complement fixation persists, the secretions of the adnexa should be bacteriologically examined.

Symptomless Syphilis in White Mice.—Karrenberg's extensive report presents clinical, histologic, biologic and serodiagnostic data which he obtained in studies on approximately 700 animals. In summing up his observations he states that syphilitic infection in white mice is symptomless, at least as far as it can be ascertained by macroscopic observation. Even infection with large doses does not produce manifestations of disease. However, a symptomless infection of mice is possible by various methods; the only requirements are a certain minimum dose of virus and a sufficiently long contact between the virus and the organism. A connection between the quantity of the virus and the rapidity of infection is not demonstrable. In regard to the detection of the symptomless infection, it is stated that the serodiagnostic methods are practically valueless. At the site of infection the pathogenic organisms are demonstrable for various lengths of time. By means of staining they are longer demonstrable than in the dark field. Outside of the implant it is never possible to demonstrate spirochetes either by means of staining or by the dark field method. The lymph nodes of mice show in syphilitic infection about the same changes that are found in rabbit and in human syphilis. As indicated in biologic experiments, they become involved quite early and remain a virus reservoir. Histologic examination of the lymph nodes reveals no signs indicative of a syphilitic infection; however, in many instances a nonsyphilitic intumescence of the lymphatic apparatus is observable. The spleen and liver likewise become involved quite early and remain infectious for considerable periods, but histopathologic changes are absent. Although, in syphilis of rabbits, Spirochaeta pallida does not enter the brain, this does take place in mice. Moreover, the spirochetes that enter the brain of mice may become neurotropic in that, when they are reinoculated into rabbits, they have a tendency to enter the brain of rabbits. Macroscopic and microscopic examinations of lungs and kidneys reveal no involvement of these organs.

Bronze Phlegmon After Renal Operations.—Meyer describes a type of gaseous phlegmon which he has observed as a complication of renal operations and which he calls bronze phlegmon because of the large bronze-colored spots which appear near the incision. The clinical picture starts with a rise of temperature within twelve hours after operation and a slight tension and reddening visible only to the experienced eye. Within twenty-four hours, bronze spots appear 5 to 10 cm. from the incision. The patient complains of tension pains; the pulse declines. On opening the wound one finds a brownish discoloration of the musculature; it is bloodless and gas bubbles rise from it. If the wound is not opened at this time, the phlegmon develops rapidly, accompanied by a circulatory collapse, sudden anuria and intestinal paralysis; the rest nitrogen may rise to 150 mg. The author reports two cases of extirpation of the kidney and two pyelotomies performed with strict asepsis in which bronze phlegmons developed. The content of the renal pelvis was sterile in three of the cases and the catgut was sterile in all cases. The author has observed gas phlegmons only in patients with adhesions of the renal pelvis and thinks the anaerobic organism causing the infection must be latent in these perirenal adhesions. These cases show that the wound should be left open in renal operations, even simple pyelotomies, if adhesions are found. A tampon should be inserted into the wound and wire sutures applied to the deep musculature, which are not tied until after a few days. If the wound is closed at operation, careful examination must be made the same day. If there is the slightest tension or redness around the wound or a rise in temperature, examination should be repeated the next day and if any of the symptoms of gas phlegmon exist, especially bronze spots, the wound should be opened immediately.

Relation of Renal Capsules to Parenchyma.—In experimental investigations of the relation between the parenchyma, the fibrous capsule and the adipose capsule of the kidney, Orth injected dye into the renal parenchyma and capsule in thirty animals. The dye injected into the fibrous capsule remains in it and never enters the renal parenchyma but does spread toward the adipose capsule. In injection of the parenchyma, a part of the dye goes into the parenchyma and outward toward the capsule. If the injection is made deeper in the medulla, the dye also goes toward the hilus into the lymph nodes located there. A part of the dye is taken up by cells, at first mostly by leukocytes, later mostly by connective tissue cells. A certain affinity between the epithelial cells of the kidney and the abundance of cells in the inner layer of the capsule probably takes part in these procedures. From these experiments several practical conclusions may be drawn. Abscesses of the adipose capsule almost never penetrate into the renal parenchyma; the fibrous capsule in a certain sense constitutes a protective barrier. Storage of dyes takes place in the cortex, and the capsule and also passes over into the adipose capsule. This applies also to the spread of bacteria by the intravenous route. A primary suppuration of the adipose capsule with secondary participation of the kidney may exist, but the spread of suppuration from the kidney to the adipose capsule is more certain. Even the latter is not a frequent occurrence, according to the author's observations.

Continuous Drainage in Postoperative Treatment of Infected Kidney.—Mutschler thinks that continuous direct renal drainage with regular systematic irrigation of the kidney is an easier and more effective way of combating infection after operation on an infected calculous kidney than the customary method. Drainage in two directions permits a more thorough cleansing of the renal pelvis and removal of inflammatory products, which play an important part as crystallization centers for recurrent formation of calculi. In the majority of his cases, drainage was accomplished through the renal parenchyma. Mechanical cleansing was combined with an acidification therapy aimed at inhibiting the growth of bacteria by production of an acid urine. Dilute hydrochloric acid was administered locally and also orally. Irrigation, starting with 1 or 2 cc. and gradually increased to 20 cc., was given from two to three times daily. The common urinary disinfectants were also extensively used. Treatment lasted between two and three months and one and two years and was usually continued at home after the first four or six weeks. This method can be used in all cases of renal lithiasis in which conservative operation can still be carried out. The therapy is most successful in cases presenting congestion of the kidney, moderate enlargement of the renal pelvis and retention of urine. In cases of bilateral renal lithiasis, this treatment can be used on the kidney operated on first and the degree of recovery used to determine the time for the second operation. No disturbances have been noted as a result of continuous drainage. In the majority of cases a pronounced improvement of the urine and the renal function was observed. There was only one recurrence. It is too early for a final judgment of this therapy.

Diagnosis of Perinephric Abscess.—Vogl shows that if a perinephric abscess is thought of, its diagnosis is not difficult, for in all cases of his own observation it was recognized during the first examination. The symptoms are few but characteristic. The main symptom is the deep painfulness in the renal region, which is detected by a short, firm blow on the lumbar musculature. Examination of the urine gives negative results, but fever and leukocytosis are always high. If the previous history reveals furuncles and other cutaneous suppurations, this is also a significant factor. Early diagnosis of the perinephric abscess is significant because it makes an early operative treatment possible, which in turn leads to rapid recovery. Spontaneous recovery is rare and should therefore not be relied on. In septic cases that are not quite clear, the paranephric abscess must be looked for. Since the subjective symptoms are either slight or entirely absent, localization of the abscess is difficult and usually is possible only by renal succussion. Patients in whom the abscess perforates early into the costovertebral angle or into the trigonum lumbale generally consult the surgeon on account of the visible swelling and fluctuation, but, in the great majority of cases in which the perinephric abscess becomes manifest as an indistinct febrile condition, the recognition by the practitioner is of great importance.

Kehrer's Sign in Brain Tumor.—Brennscheidt calls attention to Kehrer's sign, which, since he has watched for it, he has observed in all cases of cerebral tumor. The sign is a typical reaction of the patient to pressure on the so-called deep occipital point, which corresponds to the point of exit of the greater occipital nerve. As a result of the pressure the patient feels a severe pain at this point and, in order to escape it, he jerks his head backward and to the side, at which the pressure is exerted. In evaluating the symptom, Kehrer puts more stress on the flight movement than on the sensation of pain. The author asserts that occasionally the sign is an early symptom; that is, it is elicitable before other signs of cerebral tumor (choked disk and retardation of pulse) become manifest. A case of which the clinical history is given is noteworthy because in spite of the decompressive trepanation, and although choked disk was absent, Kehrer's sign was clearly perceptible. Following ventricular puncture it was less noticeable, and after operative removal of the tumor it disappeared entirely.

Postoperative Peptic Ulcer.—Zukschwerdt and Eck relate their observations in ninety-three cases of postoperative peptic ulcers. They found that roentgenoscopy and fractional withdrawal of the gastric contents make a definite diagnosis possible in nearly all cases. Perforation into adjoining organs is quite frequent, but the incidence of a colonic fistula decreases with the improvement of the diagnostic methods. The average interval between the operation and the development of the postoperative ulcer is eighteen months. On the basis of studies on the incidence of peptic ulcers after the different surgical methods, the authors give the following rules for the prophylaxis: 1. Only such surgical methods should be employed in the treatment of gastric and duodenal ulcers as effect a considerable limitation of the gastric secretion; that is, the extensive resection according to the first or second operation of Billroth. Among the ninety-three cases of peptic jejunal ulcer there were sixty-eight in which the resection would have been possible in the first operation, and thus the peptic jejunal ulcer probably could have been avoided. 2. Even ulcers that seem to be cicatrized should be resected. In two cases of this type the authors performed only a gastro-enterostomy in order to overcome the stenosis, but a peptic jejunal ulcer developed soon afterward. 3. At the anastomosis, a stenosis should by all means be prevented. For the gastro-intestinal anastomosis, the uppermost loop of the jejunum that can possibly be used should be employed. 4. All operations that result in prolongation of the chemical phase of the gastric secretion, such as exclusion of the pylorus, should be avoided. 5. If resection for exclusion is resorted to, the entire antrum and a large portion of the fundus should be removed, a procedure which the authors consider advisable only in case of duodenal ulcer: if this cannot be done, they recommend a jejunostomy as preparation for the radical operation. 6. All patients who have undergone a gastric operation should receive dietetic after-treatment and should be kept under observation for a considerable time after discharge from the hospital, so that, if a peptic jejunal ulcer should develop, it could be recognized and treated in the incipient stage, and severe complications (perforation or gastrocolic fistula) prevented.

Hyperchromic Anemia in Chronic Disorders of Pancreas.—On the basis of reports in the literature and of two cases from his own observation, Brugsch concludes that anemias, *frequently with increased color index and with increased* blood regeneration, may develop in severe, chronic pancreatic disturbances with disordered external secretion of the pancreas. The clinical aspects of these forms of anemia resemble greatly those of pernicious anemia. True pernicious anemia may likewise follow chronic disturbances of the pancreas, and there is a possibility that in these cases the disorder of the pancreas is the inciting cause. By means of special methods of examination, slight functional disturbances of the pancreas are more often demonstrable in pernicious anemia than was formerly assumed. However, the pathologico-anatomic aspects are usually not characteristic.

Clinical Aspects and Pathology of Cystic Liver.—The clinical history reported by Blum and Müller is noteworthy because of the unusually large size of the cysts. The weight of the liver, including the contents of the cysts, was 16 Kg. Another unusual aspect was the absence of disturbances in the function of the liver during a long period of observation. The gonorrheal prostatitis frequently exists, but the authors think that gonorrheal foci of a different localization are rarely detected by the complement fixation reaction. They consider it advisable to subject every gonorrhea patient who has had a prostatitis to a complement fixation test six months and twelve months after completion of the treatment; if complement fixation persists, the secretions of the adnexa should be bacteriologically examined.

Symptomless Syphilis in White Mice. — Karrenberg's extensive report presents clinical, histologic, biologic and serodiagnostic data which he obtained in studies on approximately 700 animals. In summing up his observations he states that syphilitic infection in white mice is symptomless, at least as far as it can be ascertained by macroscopic observation. Even infection with large doses does not produce manifestations of disease. However, a symptomless infection of mice is possible by various methods; the only requirements are a certain minimum dose of virus and a sufficiently long contact between the virus and the organism. A connection between the quantity of the virus and the rapidity of infection is not demonstrable. In regard to the detection of the symptomless infection, it is stated that the serodiagnostic methods are practically valueless. At the site of infection the pathogenic organisms are demonstrable for various lengths of time. By means of staining they are longer demonstrable than in the dark field. Outside of the implant it is never possible to demonstrate spirochetes either by means of staining or by the dark field method. The lymph nodes of mice show in syphilitic infection about the same changes that are found in rabbit and in human syphilis. As indicated in biologic experiments, they become involved quite early and remain a virus reservoir. Bronze Phlegmon After Renal Operations. — Meyer describes a type of gaseous phlegmon which he has observed as a complication of renal operations and which he calls bronze phlegmon because of the large bronze-colored spots which appear near the incision. The clinical picture starts with a rise of temperature within twelve hours after operation and a slight tension and reddening visible only to the experienced eye. Within twenty-four hours, bronze spots appear 5 to 10 cm. from the incision. The patient complains of tension pains; the pulse declines. On opening the wound one finds a brownish discoloration of the musculature; it is bloodless and gas bubbles rise from it. If the wound is not opened at this time, the phlegmon develops rapidly, accompanied by a circulatory collapse, sudden anuria and intestinal paralysis; the rest nitrogen may rise to 150 mg. The author reports two cases of extirpation of the kidney and two pyelotomies performed with strict asepsis in which bronze phlegmons developed. The content of the renal pelvis was sterile in three of the cases and the catgut was sterile in all cases. The author has observed gas phlegmons only in patients with adhesions of the renal pelvis and thinks the anaerobic organism causing the infection must be latent in these perirenal adhesions. These cases show that the wound should be left open in renal operations, even simple pyelotomies, if adhesions are found. A tampon should be inserted into the wound and wire sutures applied to the deep musculature, which are not tied until after a few days. If the wound is closed at operation, careful examination must be made the same day. If there is the slightest tension or redness around the wound or a rise in temperature, examination should be repeated the next day and if any of the symptoms of gas phlegmon exist, especially bronze spots, the wound should be opened immediately.

Relation of Renal Capsules to Parenchyma.—In experimental investigations of the relation between the parenchyma, the fibrous capsule and the adipose capsule of the kidney, Orth injected dye into the renal parenchyma and capsule in thirty animals. The dye injected into the fibrous capsule remains in it and never enters the renal parenchyma but does spread toward the adipose capsule. In injection of the parenchyma, a part of the dye goes into the parenchyma and outward toward the capsule. If the injection is made deeper in the medulla, the dye also goes toward the hilus into the lymph nodes located there. A part of the dye is taken up by cells, at first mostly by leukocytes, later mostly by connective tissue cells. A certain affinity between the epithelial cells of the kidney and the abundance of cells in the inner layer of the capsule probably takes part in these procedures. From these experiments several practical conclusions may be drawn. Abscesses of the adipose capsule almost never penetrate into the renal parenchyma; the fibrous capsule in a certain sense constitutes a protective barrier. Storage of dyes takes place in the cortex, and the capsule and also passes over into the adipose capsule. This applies also to the spread of bacteria by the intravenous route. A primary suppuration of the adipose capsule with secondary participation of the kidney may exist, but the spread of suppuration from the kidney to the adipose capsule is more certain. Even the latter is not a frequent occurrence, according to the author's observations.

Continuous Drainage in Postoperative Treatment of Infected Kidney. — Mutschler thinks that continuous direct renal drainage with regular systematic irrigation of the kidney is an easier and more effective way of combating infection after operation on an infected calculous kidney than the customary method. Drainage in two directions permits a more thorough cleansing of the renal pelvis and removal of inflammatory products, which play an important part as crystallization centers for recurrent formation of calculi. In the majority of his cases, drainage was accomplished through the renal parenchyma. Mechanical cleansing was combined with an acidification therapy aimed at inhibiting the growth of bacteria by production of an acid urine. Dilute hydrochloric acid was administered locally and also orally. Irrigation, starting with 1 or 2 cc. and gradually increased to 20 cc., was given from two to three times daily. The common urinary disinfectants were also extensively used. Treatment lasted between two and three months and one and two years and was usually continued at home after the first four or six weeks. This method can be used in all cases of renal lithiasis in which conservative operation can still be carried out. The therapy is most successful in cases presenting congestion of the kidney, moderate enlargement of the renal pelvis and retention of urine. In cases of bilateral renal lithiasis, this treatment can be used on the kidney operated on first and the degree of recovery used to determine the time for the second operation. No disturbances have been noted as a result of continuous drainage. In the majority of cases a pronounced improvement of the urine and the renal function was observed. There was only one recurrence. It is too early for a final judgment of this therapy.

Diagnosis of Perinephric Abscess.—Vogl shows that if a perinephric abscess is thought of, its diagnosis is not difficult, for in all cases of his own observation it was recognized during the first examination The symptoms are few but characteristic. The main symptom is the deep painfulness in the renal region, which is detected by a short, firm blow on the lumbar musculature Examination of the urine gives negative results, but fever and leukocytosis are always high If the previous history reveals furuncles and other cutaneous suppurations, this is also a significant factor. Early diagnosis of the perinephric abscess is significant because it makes an early operative treatment possible, which in turn leads to rapid recovery. Spontaneous recovery is rare and should therefore not be relied on. In septic cases that are not quite clear, the paranephric abscess must be looked for. Since the subjective symptoms are either slight or entirely absent, localization of the abscess is difficult and usually is possible only by renal succussion. Patients in whom the abscess perforates early into the costovertebral angle or into the trigonum lumbale generally consult the surgeon on account of the visible swelling and fluctuation, but, in the great majority of cases in which the perinephric abscess becomes manifest as an indistinct febrile condition, the recognition by the practitioner is of great importance.

Kehrer's Sign in Brain Tumor.—Brennscheidt calls attention to Kehrer's sign, which, since he has watched for it, he has observed in all cases of cerebral tumor. The sign is a typical reaction of the patient to pressure on the so-called deep occipital point, which corresponds to the point of exit of the greater occipital nerve. As a result of the pressure the patient feels a severe pain at this point and, in order to escape it, he jerks his head backward and to the side, at which the pressure is exerted. In evaluating the symptom, Kehrer puts more stress on the flight movement than on the sensation of pain The author asserts that occasionally the sign is an early symptom; that is, it is elicitable before other signs of cerebral tumor (choked disk and retardation of pulse) become manifest. A case of which the clinical history is given is noteworthy because in spite of the decompressive trepanation, and although choked disk was absent, Kehrer's sign was clearly perceptible. Following ventricular puncture it was less noticeable, and after operative removal of the tumor it disappeared entirely.

Postoperative Peptic Ulcer.—Zukschwerdt and Eck relate their observations in ninety-three cases of postoperative peptic ulcers. They found that roentgenoscopy and fractional withdrawal of the gastric contents make a definite diagnosis possible in nearly all cases. Perforation into adjoining organs is quite frequent, but the incidence of a colonic fistula decreases with the improvement of the diagnostic methods The average interval between the operation and the development of the postoperative ulcer is eighteen months. On the basis of studies on the incidence of peptic ulcers after the different surgical methods, the authors give the following rules for the prophylaxis 1. Only such surgical methods should be employed in the treatment of gastric and duodenal ulcers as effect a considerable limitation of the gastric secretion, that is, the extensive resection according to the first or second operation of Billroth Among the ninety-three cases of peptic jejunal ulcer there were sixty-eight in which the resection would have been possible in the first operation, and thus the peptic jejunal ulcer probably could have been avoided 2 Even ulcers that seem to be cicatrized should be resected In two cases of this type the authors performed only a gastro-enterostomy in order to overcome the stenosis, but a peptic jejunal ulcer developed soon afterward. 3 At the anastomosis, a stenosis should by all means be prevented For the gastro-intestinal anastomosis, the uppermost loop of the jejunum that can possibly be used should be employed 4 All operations that result in prolongation of the chemical phase of the gastric secretion, such as exclusion of the pylorus, should be avoided. 5 If resection for exclusion is resorted to, the entire antrum and a large portion of the fundus should be removed, a procedure which the authors consider advisable only in case of duodenal ulcer; if this cannot be done, they recommend a jejunostomy as preparation for the radical operation 6. All patients who have undergone a gastric operation should receive dietetic after-treatment and should be kept under observation for a considerable time after discharge from the hospital, so that, if a peptic jejunal ulcer should develop, it could be recognized and treated in the incipient stage, and severe complications (perforation or gastrocolic fistula) prevented

Hyperchromic Anemia in Chronic Disorders of Pancreas.—On the basis of reports in the literature and of two cases from his own observation, Brugsch concludes that anemias, frequently with increased color index and with increased blood regeneration, may develop in severe, chronic pancreatic disturbances with disordered external secretion of the pancreas. The clinical aspects of these forms of anemia resemble greatly those of pernicious anemia. True pernicious anemia may likewise follow chronic disturbances of the pancreas, and there is a possibility that in these cases the disorder of the pancreas is the inciting cause. By means of special methods of examination, slight functional disturbances of the pancreas are more often demonstrable in pernicious anemia than was formerly assumed. However, the pathologico-anatomic aspects are usually not characteristic.

Clinical Aspects and Pathology of Cystic Liver.—The clinical history reported by Blum and Muller is noteworthy because of the unusually large size of the cysts. The weight of the liver, including the contents of the cysts, was 16 Kg. Another unusual aspect was the absence of disturbances in the function of the liver during a long period of observation. The patient reached the age of 83 years, and the changes in the liver could be traced back twenty-five years. This shows to what extent the organism is capable of adjusting itself to changes in the vital organs.

Raw, Salt-Free Diet and Heat Regulation.—Eimer and Kaufmann point out that it is generally assumed that, since in perspiration not only water but also sodium chloride is eliminated, the heat regulation of human beings can be adequate only if that which is lost is quickly replaced; that is, in addition to large quantities of fluids, considerable amounts of sodium chloride have to be taken. On the other hand, a person who does not add sodium chloride to his food, that is, one who lives on a diet that is deficient in sodium chloride, is supposedly less efficient in hot weather, because he does not have the amount of perspiration that is necessary for heat regulation. Contrary observations on persons living on a salt-free, raw diet, induced the authors to make comparative tests on the heat regulation and sweat secretion of persons receiving diets with high, with normal, or with low sodium chloride content. It was found that persons who received a sodium chloride deficient, raw diet tolerate the sweating bath generally better than others. The perspiration sets in later, the skin and body temperatures do not rise so high, the quantity of perspiration is less, and its percental as well as absolute sodium chloride content is lower. The decreased sodium chloride elimination in the perspiration, like the decrease in the sodium chloride content of the urine, indicates an adaptation of the organism to the decreased sodium chloride intake. However, it may also explain the functional improvement in the heat regulation in that it accelerates the evaporation of the sweat. Other possible causes of the improved heat regulation during raw diet may be increased elimination of heat by conduction and particularly by radiation. The latter may be due to a decreased water and sodium chloride content, or to a better blood perfusion of the skin (vasomotor heat regulation). On the other hand, protein deficiency, abundant mineral content (especially potassium), and the influence of the diet on the sympathetic nervous system may also be important factors.

Hypoglycemia Following Irradiation of Pancreas.—In experiments on rabbits, Terbrüggen and Heinlein observed that by means of roentgen irradiation of the pancreas a lethal hypoglycemia can be produced. In the excretory portion of the pancreas degeneration was noted, whereas the islands of Langerhans were well preserved or even hypertrophic. In lethal hypoglycemia the glycogen disappears completely from the liver, from the muscles and from other organs. However, if during the hypoglycemic condition large amounts of dextrose are administered, the hypoglycemic symptoms, such as convulsions, hypothermia and venous collapse, disappear, and glycogen accumulates in the liver and in the muscles. An atrophy of the fat tissues of various organs was likewise noted in the hypoglycemic condition; only Kupffer's stellate cells contained fat droplets. In the brain and in the other organs, manifestations of degeneration were absent but there was stasis in the capillaries. It is as yet not definitely decided whether in hypoglycemic conditions the reduced rapidity of the sugar metabolism influences the central nervous system directly, or whether the excessive quantities of insulin produce the central nervous symptoms indirectly by way of the vessels.

Emulsive Tendency of Serum During Gestation.—In order to find an explanation for the rapid increase in the fat tissues in certain physiologic and pathologic processes, Eufinger reasoned that in such conditions the body fluids contain substances that promote emulsification of fat with water, and that the absorption of fat mixtures with high water content by the subcutaneous tissues and by other organs is thus facilitated. He also reasoned that, in the sudden increase in fat tissues that in some women sets in during pregnancy and lactation, water retention plays an important part. He then describes tests that he made on 310 pregnant women. On the basis of these tests he concludes that with advancing pregnancy the emulsive capacity of the serum increases. This increase in the emulsive power he considers to be the result of qualitative and quantitative changes in emulsive substances, particularly in cholesterol. He also thinks that the increased emulsification capacity of the serum is perhaps one of the causes for the changes in the water economy and for the tendency to edema formation that are frequently observable in pregnant women.

Deep Phlegmon of Neck.—Krecke sums up his discussion of the deep phlegmon of the neck as follows: 1. The deep phlegman of the neck is located in the loose tissue between the vascular sheath and the cervical organs, which is shut off externally by the taut cervical fascia. 2. It is dangerous because it may lead to suppurative mediastinitis and, by producing an edema of the glottis, may be the cause of sudden death. 3. The surest sign of deep cervical phlegmon is the board hard infiltration of the side of the neck with only slight involvement of the skin. 4. The location of the pus is indicated by the greatest sensitivity to pressure but, on account of the taut fascia, fluctuation is nearly always absent and should not be waited for. 5. Deep phlegmon of the neck should be treated by prompt opening. Electric surgery is most suitable for this purpose.

Rare and New Forms of Leukoplakia Oris.—In enumerating rare forms of oral leukoplakia, Ullmann calls attention to those which occasionally develop after arsenic or after gold therapy and cites one case in which severe oral leukoplakia followed the therapeutic use of arsenic and of gold. He then discusses the leukoplakia that is caused by galvanic currents developing in the oral cavity as the result of the use of several kinds of metals in dental prostheses, such as amalgam fillings, gold crowns and metal clamps. The presence of two or of several metals in the acid oral secretion produces galvanic currents that are readily detectable with the micro-amperemeter. Although the currents are weak, their constant action represents a considerable irritation. Moreover, the metals gradually disintegrate and by this also irritate the oral mucous membrane. For the treatment and prevention of the changes caused by the galvanic irritation, the author recommends that amalgam fillings should be replaced by cement or porcelain and that metal clamps and prostheses should be made of the same type of gold alloy.

Tuberculosis of Stomach.—Pop and Hanganutiu report a case of gastric tuberculosis and discuss the difficulty of differentiating between tuberculous and malignant gastric tumors In roentgenologic examination of the patient, the stomach had the appearance of being amputated, as its horizontal portion was almost entirely lacking This amputation ended with an almost linear contour In the region of this lacunar border, a mobile resistance could be palpated The barium was retained in the stomach after seven hours On the basis of these and other clinical observations a diagnosis of pyloristenosis due to tuberculous or malignant tumor was made Pylorogastrectomy was performed Histologic examination of the resected portion of the stomach and of the perigastric tumors confirmed the tuberculous nature of the gastric picture revealed at laparotomy From this case and four others previously reported the authors conclude that there are no roentgenologic criteria for differential diagnosis of tuberculosis of the stomach and cancer of the stomach, especially malignant stenosis Tuberculosis of the stomach usually leads to tumor formation, which rapidly causes a stenosis that is curable only surgically In malignant stenosis the constriction is produced by neoplastic infiltration of the pyloric wall In this case the roentgenologic picture shows an amputation of the pylorus or a lacunar appearance of the curvatures The lacunar appearance is caused by the borders of the tumors, which have irregular outlines In tumor-like tuberculous pyloristenosis the roentgenologic picture is the same with the exception that the boundaries of the tumor have a straight outline, that is, the pylorus amputation is linear Hypersecretion is always more pronounced in tuberculous than in cancerous pyloristenosis This is because the course of tuberculous stenosis is a slow one The infiltration of the stomach in all of the authors' cases did not end with the pylorus but extended to the duodenum, transforming it entirely or in part into a rigid tube For this reason one should examine every pyloristenosis minutely, also making use of duodenoscopy A duodenum with the appearance of a rigid tube points to tuberculosis, even if the clinical picture resembles malignant stenosis, as a carcinoma never extends to the duodenum

Roentgenogram of Urinary Passages in Pregnancy.—Jacobi directs attention to the ureteral dilatation that during the second half of gestation is detectable by roentgenoscopy in nearly 80 per cent of pregnant women As the main cause of this dilatation he considers the reduced tonus of the ureter, which is a partial manifestation of the general loss in tonicity characteristic for the period of gestation Moreover, the enlarging uterus exerts pressure on the ureter and thus the ureter may even present the aspects of stasis But as proof that the uterine pressure is not the only cause of the ureteral dilatation during pregnancy, the author cites the fact that in other space limiting processes, such as in the case of large tumors, dilatation is rarely observable Pyelitis presents changes in the roentgenogram only in the most severe cases, and these pyelitic changes usually appear on the renal calices and thus they differ from the physiologic pregnancy changes The roentgenologic examination of women after confinement gives valuable information, because the ureteral dilatation that is a more or less physiologic aspect of pregnancy recedes simultaneously with the postpartal uterine involution or at least soon thereafter The pyelitic changes, however, persist for longer periods, for after weeks and even after months the roentgenogram still shows a dilatation of the ureters The conclusion that the author draws from this is that in women who have had pyelitis a new pregnancy must be prevented until all clinical and roentgenologic changes have disappeared

Hemato-Encephalitic Barrier in Schizophrenia.—In the study of the hemato encephalitic barrier, Gilbo used the method of Walter-Hauptmann Within a period of six days the patient received 150 cc of a 7 per cent solution of sodium bromide On the seventh day the blood and the cerebrospinal fluid were examined The proteins were precipitated in the fluid and serum by trichloracetic acid and then to the filtrate was added several drops of a 1 per cent solution of gold chloride, which in contact with the bromine gave the solution a brownish-yellow color The bromine content was determined colorimetrically The ratio between the bromine in the blood and the spinal fluid was expressed as a coefficient of permeability Among ninety-six patients with schizophrenia examined in this way, twelve were catatonic and seven were paranoiac forms The author concludes that the hemato-encephalitic barrier in schizophrenia may be raised and lowered depending on the form of the disease In catatonic forms there is a tendency for a decrease in the coefficient of permeability (PQ) and therefore an increase in the permeability of the barrier, while in paranoiac forms the coefficient of permeability is increased During actively progressive states of schizophrenia the barrier is low, while in defective states it is high When the disturbance has a tendency to remission, the coefficient of permeability is low

Treatment of Deformities Following Poliomyelitis.—Uarovoy-Yakobson states that, in the absence of good and sufficient treatment in the presence of deformation and contracture a disturbance in the function of one or several muscle groups following acute poliomyelitis may lead to complex static and dynamic disturbances He cites eight personal observations of paralysis of the thigh muscles Insufficient and incorrect treatment may be followed by flexion, pronation and rotation contracture of the coxalgic pelvis, flexion contracture of the knee joints, genu valgum, pes valgus, or pes equinovalgus, prolapsed pelvis in a paralyzed state and bent forward, scoliosis, and lordosis of the spine, as well as marked deviation from the static and the dynamic norm The author believes that prophylactic treatment would be aided by a clearer understanding of the pathogenesis of deformation, contracture and static and dynamic disturbances Kinesitherapy may be supplemented by orthopedic surgery

Neurogenous Form of Muscular Atrophy of Charcot-Marie.—Pomerantsev reports six personal observations of patients with a typical clinical picture of Charcot-Marie and with neurogenous atrophy of muscles. Some authors believe that the chief etiologic factor of this disease is an hereditary degeneration. Three of the patients were brothers, who reported that the disease had also affected a fourth brother; all were from 28 to 33 years of age. One patient was the daughter of first cousins (the author suggests a recessive factor of inheritance); another inherited the disease from her mother, while the sixth patient reported that this disease was an hereditary characteristic of many of the male members of the family. All the patients had articular disturbances which began in the peroneal group of muscles. Disturbances in reflex action depended on the severity of the articular insufficiency. Fibrillation was present in one instance, while vibration and deep sensation were other striking symptoms. There was a disturbance in the sympathetic nervous system and there were also changes in reaction of degeneration, which serve to distinguish myopathic from neuromyelopathic forms. The course of the disease was slow and did not prevent the patients from working. The treatment was the same as that incorporated in chronic degenerative polyneuritis; namely, complete rest in bed, baths, massage, individual gymnastics, rhythmic faradization and Bergonié's treatment.

*Peptic Ulcers in Meckel's Diverticulum. H. Wulff.—p. 449.
*Treatment of Gastric Ulcer and Duodenal Ulcer in First Medical Clinic. I. Holmgren.—p. 458.
Origin and Localization of Traumatic Rupture of Bladder in Connection with Observed Case. A. B. Sjövall.—p. 467.

Peptic Ulcers in Meckel's Diverticulum.—Wulff tabulates forty-two microscopically verified cases (including one personal case) of ulcers in Meckel's diverticulum lined with gastric mucous membrane. The condition, he says, occurs almost exclusively in children and younger persons and usually in males. Hemorrhages by the rectum, frequently marked, not infrequently a clear red, are the most common and often the only symptom in the history in ulcers in Meckel's diverticulum. In only two of the cases was diagnosis made before operation. With ulcers in this localization, roentgen examination does not seem to be of great value in diagnosis.

Treatment of Gastric Ulcer.—Instead of the hypoalimentation treatment of simple ulcers, Holmgren uses a suralimentation method. He has found that hemorrhages from ulcers which do not yield to the usual dietetic treatment cease on a more liberal diet; that the ulcer symptoms disappear as rapidly as they do on a stricter regimen, which was also the case with the roentgenologic niches, and that the time of convalescence is notably shortened.

Blood Types in Forensic Work in Medicolegal Institute: Review. K. Sand.—p. 610.
**Status of Problem in Application of Human Blood Types in Paternity* Cases. O. Thomsen.—p. 615.

Orbital Phlegmons.—Møller reviews the diagnosis and treatment of orbital complications in sinus disorders, using the term orbital phlegmons as a convenient group designation without the involvement of orbital phlegmons in the stricter sense in all cases. Of the seven grave cases reported, the first, while presenting the same picture of edema of the eyelids as the others, resulted from a thrombosis of the cavernous sinus. The six cases were due to sinus disease that gave symptoms of an orbital phlegmon, three also with endocranial disorders which caused death. These cases represent the various complications which, according to the author, may be expected—subperiosteal abscess in the orbit, diffuse phlegmon without the formation of abscesses, optic neuritis and other endophthalmic changes, meningitis, and brain abscess, together with more superficial gravitation abscesses.

Human Blood Types in Paternity Cases.—Thomsen states that the distinction between the two modifications of type A (A_1 and A_2) is necessary because in certain instances it allows the exclusion of a paternity which cannot be excluded if A is considered as an undivided entity. Since the A_1 factor dominates over the A_2, the latter may be hidden by A_1, while A_1 can never be hidden by A_2. In all cases in which the exclusion of paternity may depend on a latent A_2 receptor, such cases constituting about 6 per cent of all "blood type cases," the results must be accorded definitely less value than when the more stable A_1 and B receptors are concerned.

*Significance to Be Attached to Three Types of Tubercle Bacilli (Human, Bovine and Gallinaceous) as Cause of Tuberculosis in Man in Denmark. K. A. Jensen.—p. 681.
Sporadic Goiter of Genotypical Origin and Relation to Other Thyroid *Disorders. C'td. J. Bing.—p. 688.*

Three Types of Tubercle Bacilli.—Jensen says that the avian type of tubercle bacillus is of little significance as a cause of characteristic tuberculosis in man. Type determinations of forty strains in pure culture from various tuberculous conditions show that the majority of cases of pulmonary tuberculosis and of surgical tuberculosis, except tuberculosis of the lymph nodes of the neck and urogenital tuberculosis, are caused by bacilli of the human type and that most cases of tuberculosis of the lymph nodes of the neck are due to bacilli of the bovine type, as are also 19 per cent of the cases of urogenital tuberculosis, likewise 24 per cent of the cases of tuberculous meningitis (in children under 5 more than 50 per cent). Infection with the human type of tubercle bacilli seems to occur from man to man, open pulmonary tuberculosis being the preponderating source of infection; infection with the bovine type occurs almost exclusively from cattle to man, milk being the most active source of infection.
